EVOLUTION OF CHEMICALLY PROCESSED AIR PARCELS
IN THE LOWER STRATOSPHERE

ABSTRACT

Aircraft, ground-based, and satellite measurements indicate large concentrations of CIO in the lower stratosphere in and near the polar vortex (Anderson, et al., 1989; Brune et al., 1990; de Zafra, et al., 1987; Waters et al., 1993). The amount of local ozone depletion caused by these large CIO concentrations will depend on the relative rates of ozone loss and CIO recovery. CIO recovery occurs when NOx, from HNO3 photolysis, reacts with CIO to form ClONO2. We show that air parcels with large amounts of CIO will experience a subsequent ozone depletion that depends on the solar zenith angle. When the solar zenith angle is large in the middle of winter, the recovery of the CIO concentration in the parcel is slow relative to ozone depletion. In the spring, when the solar zenith angle is smaller, the CIO recovery is much faster. After CIO recovery, the chlorine chemistry has not returned to normal. The CIO has been converted to ClONO2. CIO production from further encounters with PSCs will be limited by the heterogeneous reaction of ClONO2 with water. Large ozone depletions, of the type seen in the Antarctic, occur only if there is significant irreversible denitrification in the air parcel.

INTRODUCTION

We have developed a version of our photochemistry model (Douglass et al., 1989) to calculate chemical changes occurring along the path of a stratospheric air parcel. In this study we apply the model to the simple case of a parcel which is fixed at a given latitude and altitude; 50°N and 20 km. The chemistry of the parcel is initialized by assuming that the air has been fully processed by heterogeneous reactions on the surface of NAT particles; i.e. all of the reactive nitrogen is HNO3 and all of the inorganic chlorine is CIO or Cl2O2 (Jones et al., 1990; Brune et al., 1990; Fahey et al., 1990). Parcels are started at the beginning of each month of the northern winter and spring (November through April) and are allowed to evolve chemically for 30 days. At this point, ozone loss greater than that expected from normal photochemistry has ceased. Details of the assumed initial conditions are shown in Table 1.

MODEL RESULTS

Ozone loss calculated from two model runs are shown in Figure 1. One run begins January 1 while the other begins April 1. On the first day after initialization,

Fig. 1. Calculated ozone change as a function of time after parcel initialization. Results are shown for two parcels, one initialized on January 1, the other on April 1.
both parcels have about the same CIO concentration and lose ozone at the same rate. The parcel released on April 1 experiences a longer period of sunlight and thus loses more ozone. As the parcels evolve, the one released on April 1 exhibits a rapid recovery of CIO as illustrated in Figure 2. Thus, the rate of ozone loss for the April 1 parcel diminishes each day such that by day 4, the total ozone lost is the same as that lost by the January 1 parcel despite the difference in the length of day. By day 6, the cumulative ozone loss in each of the parcels is the same and on all succeeding days, the ozone loss is greater for the parcel released on January 1. The somewhat surprising result is that the parcel which was fully processed by January 1 lost 13% of its initial ozone, while the parcel which was fully processed on April 1 lost only 7% of its initial ozone.

Fig. 2. Calculated noontime CIO mixing ratio as a function of time after parcel initialization. Actual calculated CIO exhibits a strong diurnal variation with a noon maximum.

The recovery of the CIO concentration is controlled by NO where which is generated by the photolysis of HNO. Because the parcel has a very high CIO concentration, the NO generated is rapidly converted to CIONO. For the April 1 parcel, the CIONO concentration rises rapidly to 2.5 ppbv, using up all of the available chlorine as illustrated in Figure 3. The January 1 parcel shows a slower rise, but still goes to 2.5 ppbv after 30 days. Figure 4 illustrates that the chlorine nitrate concentration rises at almost exactly the rate of the disappearance of HNO. When the CIONO concentration reaches 2.5 ppbv, no more CIO is available, and NO begins to accumulate. At the end of 30 days, the HCl concentration is barely more than 0.2 ppbv for the April 1 parcel and about 0.1 ppbv for the January 1 parcel.

The reason for the change in the relative efficiency of ozone loss to CIO recovery can be understood by examining the photolysis rates for ClO and HNO. Figure 5a shows the diurnal variation of the HNO photolysis rate on January 1 compared to April 1. Figure 5b shows the same thing for the photolysis rate of ClO. ClO, because of its near uv absorption, is photolyzed about 70% as rapidly on January 1 as on April 1. HNO, on the other hand, is photolyzed only about 35% as rapidly on January 1. For a given amount of CIO, the rate of ozone destruction by the ClO dimer cycle is determined by the ClO photolysis rate. It can be seen from Figure 5 that the sun effectively rises faster for ozone destruction than it does for CIO recovery.

Fig. 4. Comparison of calculated CIONO mixing ratio as a function of time with the rate of disappearance of HNO. When all of the chlorine is used up to form CIONO, the NO mixing ratio begins to rise.

CONCLUSION

Ozone depletion occurring in parcels of lower stratospheric air, which have been processed through a PSC, is limited by the recovery of the high ClO concentrations to chlorine nitrate. Parcels processed in the middle of winter showed more subsequent ozone depletion than those processed in the spring. A parcel which was initialized on January 1 with all of the chlorine as ClO and ClO$_2$, and all of the reactive nitrogen as HNO$_3$, lost 13% of its ozone in the next 30 days. A parcel similarly initialized on April 1, lost only 7% of its ozone in 30 days. The explanation has been shown to be related to the relative photolysis rates of ClO$_2$ and HNO$_3$, which govern the competition between ozone loss and ClO recovery.

If the chemically perturbed air from these parcels is processed through a subsequent PSC, recoversion of ClONO$_2$ to ClO cannot occur via reaction with HCl because of the slow recovery of HCl. The effect of further PSC processing will be limited by the reaction of ClONO$_2$ with water. However, if the air has been denitrified, large ozone depletions can occur because chlorine nitrate formation will be inhibited. In this case, recovery will be controlled by the resupply of active nitrogen to the parcel by mixing processes.
