MAJA VALLES AND THE CHRYSE OUTFLOW COMPLEX SITES. J. W. Rice, Department of Geography, Arizona State University, Tempe AZ 85287, USA.

Maja Valles Region: This candidate landing site is located at 19°N, 53.5°W near the mouth of a major outflow channel, Maja Valles, and two "valley network" channel systems, Maumee and Vedra Valles. This region has been mapped in detail by Rice and De Hon and is in press as a USGS 1:500,000 scale geologic map. The advantages to this site are the following: Two distinct channel forms (outflow and dendritic valley network) in one location. These channels were formed by different processes. The outflow channels are believed to have formed by catastrophic release of water and the valley networks by surface runoff and or sapping. The ideal landing site, if it could be pinpointed, would be on the fan delta complex located at the terminus of the three channels (Maja, Maumee, and Vedra Valles). The fan delta complex would be a fairly smooth surface with shallow slopes.

Water was impounded behind the wrinkle ridge system, Xanthe Scopulus, forming a temporal lake. This paleolake bed would also present itself as a safe landing site, perhaps similar to playas. Once the wrinkle ridges were breached the water flowed northeastward in the direction of the Viking 1 lander, some 350 km away.

Objectives to be analyzed in this region are (1) origin and paleohydrology of outflow and valley network channels, (2) fan delta complex composition (this deposit located in this area is one of the few deposits identified at the mouths of any channels on the planet), and (3) analysis of any paleolake sediments (carbonates, evaporites). Another advantage to this area will be any blocks and boulders that were plucked out and carried along the 1600-km course of Maja Valles. These samples would provide a virtual grab bag of lithologies. For example, the oldest mappable rock unit (Nb, Noachian basement material) and the Hesperian ridged plains (Hr) are cut by Maja Valles before it empties into Chryse. It can be argued that we will not know their exact location, which is true, but it will provide us with information about the variety of rock types on Mars by only landing in one site. Other questions to be investigated in the area are the origin of wrinkle ridges by viewing ridge walls that were incised by the outflow, streamlined islands/bars; whether they are erosional or depositional, and if the location permits view channel wall stratigraphy, fan delta stratigraphy, and perhaps send the rover up a channel mouth near the end of its mission.

This site is below the 0-km elevation datum, within the latitude restrictions (19°N), and all the objectives stated above are within the 150-km landing error ellipse. This region is also imaged at resolutions of 40–50 m/p.

The Chryse Outflow Complex Region (Ares, Tiu, Mawrth, Sinus, and Shalbatana Valles): The overall philosophy and objectives described above for the Maja Valles region apply here as well. The primary objectives here would be outflow channel dynamics (paleohydrology) of five different channel systems. One question to be answered might be whether all outflow channels are of the same origin and type. They are probably all somewhat different in terms of duration, age, source, and perhaps even origin. The grab bag philosophy of various rock types being deposited near channel mouths would apply here also. The site is located at 15°N, 35°W. However, the longitudinal coordinate can be relaxed or slid farther to either side of 35°W. Sliding the ellipse farther to the east would allow investigations of Mawrth Valles. The region near the mouth of Mawrth Valles would be of interest because this area contains material that appears to have been dissected, thus exposing the stratigraphy of what may possibly be deltaic sediments.

MARTE VALLES SITE. J. W. Rice, Department of Geography, Arizona State University, Tempe AZ 85287, USA.

This site is located at 16°N, 177°W on the flood plains of Marte Valles, which is perhaps the youngest channel system on Mars. However, the coordinates for the landing site are flexible. Moving the site more to the southwest would allow investigations of possible lacustrine sediments. The channel extends for about 3000 km from southeastern Elysium Planitia to western Amazonis Planitia. This system appears to originate within the knobby cratered material around Cerberus Rupes, a set of en echelon fractures that extend for more than 1000 km. Crater counts indicate that this system is Amazonian in age. This channel may have also acted as a spillway between paleolakes located in Elysium and Amazonis Planitia. The young age of this channel warrants investigation because of climatic implications for fluvial activity in recent geologic time. The paucity of craters makes this an excellent site in terms of safety requirements. Detailed work by Tanaka and Scott indicate that embayed craters larger than 1 km diameter appear embayed by the channeled plains unit, suggesting that it is only tens of meters thick. This material contributed to the resurfacing of the northern lowlands of the planet. Some of the objectives stated previously for the Maja Valles Region would also apply to this site (grab bag of rock types, etc.). This site is below the 0-km datum, located at 16°N, and has the young channeled plains, bars, terraces, and streamlined albedo patterns located within the 150-km landing error ellipse. Resolution coverage in some areas is as high as 13 m/p.

ALPHA PROTON X-RAY SPECTROMETER. R. Rieder1, H. Wänke1, and T. Economou2, Max-Planck-Institut für Chemie, Mainz, Germany, 2University of Chicago, Chicago, IL 60637, USA.

Mars Pathfinder will carry an alpha-proton X-ray spectrometer (APX) for the determination of the elemental chemical composition of martian rocks and soils. The instrument will measure the concentration of all major and some minor elements, including C, N, and O, at levels above typically 1%.

The method employed consists of bombarding a sample 50 mm in diameter with alpha particles from a radioactive source (50 mCi of 244Cm) and measuring (1) backscattered alpha particles (Rutherford backscatter = RBS mode), (2) protons from A(,p)B reactions (proton mode) and (3) characteristic X-rays emitted from the sample (X-ray mode). In RBS mode all elements with atomic mass greater than four are registered, thus permitting normalization of results to 100% concentration. This feature permits accurate quantitative analysis independent (within limits) of the actual measurement geometry. Data obtained from proton and X-ray modes are used to enhance selectivity of the RBS mode for the rock-forming elements Mg, Al, and Si and for heavier elements (K and Ca, Fe-group).
