ABSTRACT

In this paper we present the emitter efficiency results for the thin film 25% Ho YAG (Yttrium Aluminum Garnet, \( \text{Y}_3\text{Al}_5\text{O}_{12} \)) selective emitter from 1000-1700 K with a platinum substrate. Spectral emittance and emissive power measurements were made \((1.2 < \lambda < 3.2 \ \mu\text{m})\) and used to calculate the radiative efficiency. The radiative efficiency and power density of rare earth doped selective emitters are strongly dependent on temperature and experimental results indicate an optimum temperature \((1650 \ \text{K for Ho YAG})\) for TPV applications.

INTRODUCTION

Efficient thermophotovoltaic (TPV) energy conversion is strongly dependent on emitter performance[1]. The most promising solid state selective emitters are compounds containing elements in the Lanthanide Series (rare earths). Nelson and Parent[2,3,4] using the rare earth oxide Weisbach mantle emitter have been the most successful. A new class of rare earth solid state selective emitters, the rare earth garnets[5,6], has the potential for being efficient, as well as, more durable than the mantle type emitter. In this paper we present experimental results for the radiative efficiency of a YAG (Yttrium Aluminum Garnet, \( \text{Y}_3\text{Al}_5\text{O}_{12} \)) thin film selective emitter doped with holmium (Ho) for a temperature range of 1000 to 1700 K and compare it to the theoretical results predicted using[7].

RARE EARTH GARNET SELECTIVE EMISSER

The atomic structure of the doubly and triply charged rare earth ions such as Yb, Er, Ho, Tm, Dy, and Nd accounts for their unique spectral emission characteristics. The orbits of the valence 4f electrons, whose electronic transitions determine the spectral emission properties, lie inside the 5s and 5p electron orbits. The 5s and 5p electrons "shield" the 4f valence electrons from the surrounding ions in the crystal. As a result, the rare earth ions in the solid state have radiative characteristics much like an isolated atom in a gas and emit in relatively narrow bands rather than in a continuum as do most solids.

As already mentioned, the first successful rare earth selective emitters were the rare earth oxides. Recently rare earth doped YAG has shown excellent emissive properties[5]. Doping limits, dependent on the particular ion and crystal host may be as high as 100 at. % (complete substitution of the yttrium ion with the rare earth ion). These materials have high melting points \((1940 \ \text{C for undoped YAG})\) making them excellent candidates for a high temperature thin film selective emitter. For most of the rare earths the emission spectra is composed of emission bands in the near infrared \((0.9 < \lambda < 3.0 \ \mu\text{m})\) with relatively low emission outside these bands. For thermally stimulated emission, where the density of excited states is governed by Boltzmann equilibrium, the emission spectrum is dominated by a single emission band from the deexcitation (spontaneous emission) of the 1st level to the ground state. Since YAG can be doped with more than a single rare earth it is possible to make a thin film selective emitter with multiple emission bands. As a result, greater power density over a wider wavelength interval can be achieved than with a single rare earth dopant.[6]

The efficiency, \( \eta_E \), of a selective emitter is defined as

\[
\eta_E = \frac{Q_b}{Q_T}
\]

where \( Q_b \) is the emitted power in the emission band and \( Q_T \) is the total emitted power.

\[
Q_b = \int_{\lambda_u}^{\lambda_l} q_{\lambda} d\lambda
\]

\[
Q_T = \int_{0}^{\infty} q_{\lambda} d\lambda
\]
where $q_A$ is the spectral emissive power of the emitter, $\lambda_u$ is the short wavelength limit for the emission band and $\lambda_l$ is the long wavelength limit for the emission band. In the experiment to be described in the next section $q_A$ is measured with a spectroradiometer and $Q_b$ and $Q_f$ are measured with a pyroelectric radiometer.

**EXPERIMENTAL PROCEDURE**

The emissivity of a material is usually thought of as a property of an isothermal surface. However, for the thin film rare-earth YAG emitter from throughout the film contributes to the spectral emittance. Since significant temperature differences (210 - 260 K) exist between the front and back emitter surfaces the effect of the temperature gradient on the radiative performance of the thin film selective emitter is investigated. For the theoretical analysis the “emitter temperature” is defined by the substrate temperature, $T_s$, and the temperature gradient, $\Delta T = T_s - T_{Front}$. The average of the front and back surface temperatures, $T_{avg} = (T_s + T_{Front})/2$, in the center of the sample is used to calculate spectral emittance from the spectroradiometer intensity measurements. A radial temperature gradient of 5 K was also measured on the sample in the field of view of the pyroelectric radiometer. This variation, small in comparison to the front-back temperature gradient and other sources of experimental error, was neglected in the emittance calculations. Temperature measurements, made with type R thermocouples, had an accuracy of +/- 6K. Total power and power in the Ho YAG emission band was measured with a Laser Precision Rk-5100 radiometer calibrated to an NBS traceable standard. Normal spectral emittance, $\varepsilon_{\lambda}$, measurements were made with a spectroradiometer constructed from a 1/8 meter monochromater, a temperature controlled PbS detector, and an 800 Hz chopper calibrated with a 1273 K blackbody reference. Energy in the emission band, $Q_b$, is measured with the spectroradiometer and calculated using eq. 2. Normal spectral emittance measurement accuracy and repeatability with the blackbody reference at 1273 K was typically within 2% from 1.2 < $\lambda$ < 3.2 $\mu$m. A series of precision optical pinholes was inserted in the hole through the insulation near the specimen to reduce the measurement error from these combined effects.

Comparison of $\varepsilon_{\lambda}$ measurements and data from [8] for polished Pt foil show the error in $\varepsilon_{\lambda}$ due to reflected radiation is dependent on the specimen temperature. Raising the specimen temperature increases the intensity of the background radiation and shifts the energy distribution to shorter wavelengths. At 1640K the increase in $\varepsilon_{\lambda}$ due to reflected radiation and temperature measurement error is +0.029 @ 1.5 $\mu$m, +0.046 @ 2.0 $\mu$m, and +0.049 @ 3.0 $\mu$m. This will be the maximum measurement error for materials with high spectral reflectance (~80%) and low emittance such as platinum. However, in the Ho YAG specimen, reflectance in the emission band is less (20-70% for Ho-YAG) and the actual measurement error will be lower than the error for platinum.

**EXPERIMENTAL RESULTS**

Thin film selective emitter performance is dependent on factors such as emitter thickness and temperature, substrate emittance and rare earth dopant type and concentration[9]. For maximum emitter performance it is essential that these parameters be optimized. The experimental results presented here for the Ho YAG thin film selective emitter do not include efforts to optimize performance through optimization of these parameters. The thickness and doping level of the test specimen reflects the commercial availability of material developed for solid state lasers. Even without optimization results indicate that rare earth thin film selective emitters have potential as elements in a high efficiency TPV system.

![Figure 1](image-url)
A 1.1 mm thick, 30 mm dia. section of 25% Ho-YAG with a Pt foil substrate was used to investigate the effect of emitter temperature on radiative efficiency. Normal spectral emittance, $\varepsilon_{\lambda}$, measurements were made from $1.2 < \lambda < 3.2 \mu \text{m}$ for a series of temperatures ranging from 1000 - 1700K. The radiative efficiency, $\eta_E$, was calculated using eqs. 1, 2, 3 with $\lambda_b = 1.8 \mu \text{m}$ and $\lambda_t = 2.2 \mu \text{m}$ defining the emission band interval used to calculate $Q_B$. Finally, the experimental results for $\eta_E$ are compared to the theoretical results for $\eta_E$ calculated using [7].

Figure 2 shows the normal spectral emittance in the emission band of 25% Ho YAG ($\delta_\gamma - \delta_\delta @ 2.0 \mu \text{m}$) at three values for $T_{\text{avg}}$: 1029, 1410, and 1643 K, from $1.2 < \lambda < 3.2 \mu \text{m}$. The spectral distribution of the emitted radiation can be divided into two regions. Relatively strong emission is present from $1.8 < \lambda < 2.2 \mu \text{m}$, also the wavelength interval used to calculate $Q_B$, at the characteristic emission band. Outside the emission band the extinction coefficient for rare earth YAG is relatively low ($-0.1 \text{ cm}^{-1}$, $0.3 < \lambda < 5.0 \mu \text{m}$) and the emission in this region will be dominated by the platinum substrate.

Several important features can be discerned from this figure. First, except for variations caused by thermal line broadening, the spectral emittance in the emission band is relatively temperature invariant. Second, since the optical and radiative properties of this material in the emission band is dominated by the electronic transitions of the substitutional rare earth impurity this result is expected. Third, the increase in $\varepsilon_{\lambda}$ outside the emission band is greater than the expected increase in the spectral emittance of Pt from 1000-1700 K.

The rapid increase of $\varepsilon_{\lambda}$ outside the emission band cannot be attributed to an increase in the substrate emittance, $\varepsilon_{\lambda}$ for Pt is actually less at 1633 K than 1410 K for $\lambda = 2.0 \mu \text{m}$[8]. Data for the high temperature spectral emittance of oxide materials similar (low $\alpha_D$) to YAG such as sapphire, ALON, and spinel show that the spectral emittance of these materials is very low, $\varepsilon_{\lambda} < 0.05$, and remains essentially constant for temperatures up to 2000 K. As previously mentioned, for a given $\lambda$, the magnitude of reflected background radiation and the error in $\varepsilon_{\lambda}$ increases with $T_{\text{avg}}$. In addition, the magnitude of this error will be greater for long wavelengths. This is confirmed in fig 2. i.e. as $T_{\text{avg}}$ increases, the rate of increase in $\varepsilon_{\lambda}$ is greater below the emission band than above the emission band. This result is opposite to the expected (measured) results for $\varepsilon_{\lambda}$ vs $T_s$ for Pt[8]. The error in $\varepsilon_{\lambda}$ due to background radiation is significantly reduced from $1.8 < \lambda < 2.2 \mu \text{m}$ due to the relatively strong absorption in the emission band, also shown in fig. 2. It is important to note that the emission from YAG, however small, is effectively doubled by the reflective substrate and adds to the magnitude of $\varepsilon_{\lambda}$ at all wavelengths.

Additional measurements are planned to investigate the high temperature (up to 2000 K) spectral emittance of YAG without a substrate.

Figure 3 shows the theoretical and experimental results for the radiative efficiency, $\eta_E$. The experimental values are calculated using measured values for $Q_B$ and $Q_T$ in eq. 1. To calculate theoretical values for $\eta_E$ the experimental values of $T_s$, $\Delta T$, $\varepsilon_{\lambda}$, and the spectral extinction coefficient, $\alpha_{\lambda}$, for Ho-YAG previously reported in [5] are used in the analysis presented in [7].

The theoretical and experimental results for the temperature at which the maximum radiative efficiency occurs, 1650 K (experimental) and 1550 K (theoretical), are nearly identical however, the maximum value for $\eta_E$ at these temperatures differs by a factor of approximately 1.5. Constraints in the theoretical model require that $\varepsilon_{\lambda}$ of the substrate and $\alpha_{\lambda}$ outside the emission band be specified as constants. For the theoretical calculation of
The following values were used for $e_s$, $e_a = 0.25$ ($0 \leq \lambda < 1.8 \mu m$), $e_s = 0.19$ ($1.8 \leq \lambda < 2.2 \mu m$) and $e_s = 0.15$ ($2.2 \leq \lambda < \infty \mu m$). Actual measurements show that for Ho YAG and other aluminum garnets $\alpha_\lambda$ increases rapidly for $\lambda > 5.0 \mu m$ and remains high through the far IR. As a result $e_s$ for YAG is also expected to be high, $-0.95$ for $5.0 < \lambda < 10.0 \mu m$[10], and the additional radiation emitted at these wavelengths will increase the magnitude of $Q_T$ and reduce the experimental value for $\eta_E$ for a given $T_e$. For this analysis, the contribution of the long wavelength radiation from YAG, $q_{\lambda>5.0}$, is approximated using the Planck equation with the experimental values for $T_{avg}$ and $e_s = 0.8, 0.95$(expected emittance for YAG) - 0.15(theoretical value for $e_s$), for $5.0 \mu m < \lambda < \infty$. This result is used to modify the theoretical result for $Q_T$ and $\eta_E$ where

$$Q_T' = Q_T + q_{\lambda>5.0}$$

$$\eta_E' = \frac{Q_T'}{Q_T}$$

The effect on the emission from YAG at $\lambda > 5.0 \mu m$ on the theoretical values values for $\eta_E$, represented by $\eta_E'$, is also shown in fig 4. The effect of $q_{\lambda>5.0}$ on $Q_T'$ will be greater for lower values of $T_e$ since the amount of radiation emitted below $\lambda = 5.0 \mu m$ decreases proportionately as the temperature increases. Results for $\eta_E'$ are in good agreement with experimental values for $\eta_E$ and suggest that difference in temperature where the maximum theoretical and experimental values of $\eta_E$ occurs is due to $q_{\lambda>5.0}$.

As mentioned earlier, the emitter is not optimized with regard to thickness, Ho concentration, and substrate emittance. Using a substrate with a lower $e_s$ such as rhodium will improve $\eta_E$. Also, theory[11] indicates the optimum thickness for 25% Ho YAG is ~0.6 mm, considerably less than the 1.1 mm thick sample used for this experiment.

CONCLUSION

The first measured results for the effect of temperature on the radiative efficiency of rare earth doped thin film selective emitters confirms there is an optimum temperature for maximum emitter efficiency. Accounting for the additional long wavelength radiation($\lambda > 5.0 \mu m$) from the host material(YAG), the experimental and previously reported theoretical results for an Ho doped selective emitter are in good agreement.

REFERENCES

In this paper we present the emitter efficiency results for the thin film 25% Ho YAG (Yttrium Aluminum Garnet, $\text{Y}_3\text{Al}_5\text{O}_{12}$) selective emitter from 1000–1700 K with a platinum substrate. Spectral emittance and emissive power measurements were made ($1.2 < \lambda < 3.2 \text{ \mu m}$) and used to calculate the radiative efficiency. The radiative efficiency and power density of rare earth doped selective emitters are strongly dependent on temperature and experimental results indicate an optimum temperature (1650 K for Ho YAG) for TPV applications.
