ABSTRACT
An existing three-dimensional Navier-Stokes code (Arnold et al., 1991), modified to include film cooling considerations (Garg and Gaugler, 1994), has been used to study the effect of coolant velocity and temperature distribution at the hole exit on the heat transfer coefficient on three film-cooled turbine blades, namely, the C3X vane, the VKI rotor, and the ACE rotor. Results are also compared with the experimental data for all the blades. Moreover, Mayle's transition criterion (Mayle, 1991), Forest’s model for augmentation of leading edge heat transfer due to free-stream turbulence (Forest, 1977), and Crawford’s model for augmentation of eddy viscosity due to film cooling (Crawford et al., 1980) are used. Use of Mayle's and Forest’s models is relevant only for the ACE rotor due to the absence of shrouded cooling on this rotor. It is found that, in some cases, the effect of distribution of coolant velocity and temperature at the hole exit can be as much as 60% on the heat transfer coefficient at the blade suction surface, and 50% at the pressure surface. Also, different effects are observed on the pressure and suction surface depending upon the blade as well as upon the hole shape, conical or cylindrical.

NOMENCLATURE
\( a, b \) semi-axes of the ellipse describing the hole exit on the blade surface
\( a_1, a_2 \) coefficients in equation (1)
\( B_r \) blowing ratio \([= (\rho_U V_c)/(\rho_U U)]\)
\( c \) true chord of the blade
\( C_f \) coefficient in equation (2)
\( d \) coolant hole diameter
\( h \) heat transfer coefficient based on \((T_o - T_w)\)
\( h_o \) standard value \((= 1135.6 \text{ W/m}^2\text{-K} = 200 \text{ Btu/hr-ft}^2\text{-R})\)
\( k \) von Karman constant
\( l \) mixing length
\( L \) length of the injection pipe

Subscripts
1 at inlet
2 at exit
c for coolant (average value)
e edge of boundary layer
m maximum value
n corresponding to uncooled blade
o stagnation value
w at the blade surface
\( \infty \) local free-stream value

1. INTRODUCTION

There is a growing tendency these days to use higher and higher temperatures at the inlet to a turbine since it yields higher thermal efficiency. Modern gas turbine engines are designed to operate at inlet temperatures of 1800-2000 K, which are far beyond the allowable metal temperatures. Thus, to maintain acceptable life and safety standards, the structural elements need to be protected against the severe thermal loads. This calls for an efficient cooling system. One such cooling technique currently used for high temperature turbines is film cooling. In this technique, cooler air is injected into the high temperature boundary layer on the blade surface. Since the cooler air is bled directly from the compressor before it passes through the combustion chamber, it represents a loss in the total power output. The designer’s goal is therefore to minimize the coolant necessary to insure adequate turbine life.

To this end, considerable effort has been devoted into understanding the coolant film behavior and its interaction with the mainstream flow. The film cooling performance is influenced by the wall curvature, three-dimensional external flow structure, free-stream turbulence, compressibility, flow unsteadiness, the hole size, shape and location, and the angle of injection. Many studies on film cooling have been confined to simple geometries, for example, two-dimensional flat and curved plates in steady, incompressible flow. A survey of work up to 1971 has been provided by Goldstein (1971). While several further studies in this field have been summarized by Garg and Gaugler (1993, 1994, 1995), we will discuss some relevant ones here from the point of view of the present study.

Bergeles et al. (1980) devised a finite-difference code with a semi-elliptic treatment of the flow field in the neighborhood of the injection holes. The comparison of predicted results with experimental data on a flat plate showed poor agreement in the vicinity of the hole partly due to the assumption of a uniform coolant velocity at the hole exit. Schöning and Rodi (1987) presented a two-dimensional boundary layer model with a modification for three-dimensional elliptic flow for simulating the effects of film cooling by a single row of holes. The region near the injection was leapotted over and new profiles were prescribed at the hole exit. Dibelius et al. (1990) developed an elliptic treatment of the flow field in the neighborhood of the injection hole. Leylek and Zerkle (1994) analyzed the injection was leapotted over and new profiles were prescribed at the hole exit. Dibelius et al. (1990) developed an elliptic treatment of the flow field in the neighborhood of the injection hole. Leylek and Zerkle (1994) analyzed the interaction of film-cooling air with the main flow by a plane turbulent boundary layer, and another for a plane nozzle guide vane with two rows of holes.

Sondermann and Rodi (1987) developed a multi-block, three-dimensional Navier-Stokes code for film cooling on a flat plate using the k-ε model of turbulence in a 3-D Navier-Stokes code. They found the flow within the film-hole to be extremely complex, containing counter-rotating vortices and local jetting effects that make the flow field in this region highly elliptic. The distribution of dependent variables at the hole exit plane resulted from the interaction of three competing mechanisms, namely, counter-rotating structure and local jetting effects within the film-hole, and cross-flow blockage.

Fougeres and Heider (1994) solved the unsteady three-dimensional Navier-Stokes equations, completed by a mixing-length turbulence model, using a finite volume technique. They presented two applications of the multi-domain code; one for a single row of hot jets injected into a flat plate turbulent boundary layer, and another for a plane nozzle guide vane with two rows of staggered holes on the pressure as well as suction side of the vane. They specified uniform conditions for the coolant at entry to the injection pipe but provided no details for the coolant profiles at the hole exit. Weigand and Harasgama (1994) carried out a numerical investigation of film cooling on a turbine rotor blade using Dawes (1993) code that utilizes an unstructured solution adaptive grid methodology for solving three-dimensional Navier-Stokes equations. They discretized the plenum chamber and the injection pipe. However, a rather academic case of blowing in tangential direction was studied due to limitations of the code. As such, comparison with experimental data was not possible.

Hall et al. (1994) analyzed the shower-head film cooling on the C3X vane with a multi-block, three-dimensional Navier-Stokes code using the Baldwin-Lomax turbulence model. Taking advantage of the spanwise periodicity of the planar C3X vane, the
computational span was restricted to just one spanwise pitch of the shower-head holes. The final airfoil C-grid had over 2.1 million grid points with a 17x17 grid patch on each of the five holes. Such a grid refinement cannot be handled by present day computers if the vane were annular requiring the whole span to be analyzed, not just a slice of it. The computational domain included the injection pipe but not the plenum chamber. They specified uniform coolant conditions at entry to the injection pipe but provided no details of the coolant distribution at the hole exit.

The above survey indicates that the effect of coolant distribution at the hole exit, though important, has not yet been investigated on real turbine blades. This is precisely the objective of the present study. Herein, an existing three-dimensional Navier-Stokes code (Arnone et al., 1991), modified to include film cooling considerations (Garg and Gaugler, 1994), has been used to study the effect of coolant velocity and temperature profiles at the hole exit on the heat transfer characteristics of film-cooled turbine blades. Comparison with experimental data for a C3X vane with nine rows of film cooling holes (Hylton et al., 1988), for a VKI rotor with six rows of holes (Camci and Arts, 1990), and for the ACE rotor with three rows of holes (Norton et al., 1990), is provided.

2. ANALYSIS

The three-dimensional Navier-Stokes code of Arnone et al. (1991) for the analysis of turbomachinery flows was modified by Garg and Gaugler (1994) to include film cooling effects and Mayle’s transition criterion (Mayle, 1991). It was further modified to include Forest’s model for augmentation of leading edge heat transfer due to free-stream turbulence (Forest, 1977), and Crawford’s model for augmentation of eddy viscosity due to film cooling (Crawford et al., 1980). Briefly, the code is an explicit, multigrid, cell-centered, finite volume code with an algebraic turbulence model. The Navier-Stokes equations in a rotating Cartesian coordinate system are mapped onto a general body-fitted coordinate system using standard techniques. Viscous effects in the streamwise direction are neglected in comparison to body-fitted coordinate system using standard techniques. Viscous rotating algebraic turbulence model. The Navier-Stokes equations in an explicit, multigrid, cell-centered, finite volume code with an implicit residual smoothing are used along with a full-multigrid Eigenvalue-scaled artificial dissipation and variable-coefficient number of 5 was used to speed convergence to the steady state. A spatially varying time step along with a CFL number of 5 was used to speed convergence to the steady state. Kutta scheme developed by Jameson et al. (1981) is used to advance the flow solution in time from an initial guess to the steady state. A spatially varying time step along with a CFL number of 5 was used to speed convergence to the steady state. The algebraic model has been used satisfactorily by Boyle and Giel (1992), Ameri and Amone (1994a, b), and Boyle and Ameri (1994) for heat transfer calculations on turbine blades without film cooling, and by Hall et al. (1994), and Garg and Gaugler (1994) with film cooling. In fact, Ameri and Amone (1994b) compared the Baldwin-Lomax model and Coakley’s q-oa model against experimental data of Graziani et al. (1980), and found that the algebraic model was able to produce many of the flow features better than the two-equation model. They further state that this conclusion is strengthened when one takes into account the relative economy of computations with the algebraic model.

Moreover, Mayle’s transition criterion (Mayle, 1991) has been implemented in the code. The incoming flow in the experimental tests on the ACE rotor (Norton et al., 1990) had a turbulence intensity of 4.0%, and it is assumed constant for application of Mayle’s model. For the C3X vane and the VKI rotor, Mayle’s criterion is immaterial since the flow turns turbulent at the leading edge itself due to shower-head injection.

2.1 Forest’s Model

The strong favorable free-stream pressure gradients near the
leading edge result in laminar flow, even with high free-stream turbulence. The laminar heat transfer at the leading edge is, however, increased by the free-stream turbulence. The model of Forest (1977) was incorporated in order to account for this increase. According to this model

$$\varepsilon_M = C_p \frac{\kappa T u_{in} U_c}{\nu}$$  \hspace{1cm} (2)

where the mixing length, $\ell$, is defined as

$$\ell = \min(k, \nu, 0.08 \delta)$$

While several ways to calculate the boundary layer thickness were tried following Davis et al. (1988), it was found that the best method was to relate it to the momentum thickness whose calculation is described later on. The coefficient $C_p$ is found from

$$C_p = \frac{0.75}{1 + 0.04|\lambda|}$$

where

$$\lambda = \frac{\theta^2 dU_c}{\nu}$$

The momentum thickness is calculated using Thwaites' method, as given by White (1974). According to this, the momentum thickness at a location $s$, along the blade surface is given by

$$\Theta^2(s) = \frac{0.45 \nu}{U_c^2} \int_{0}^{s} U_c dS$$

The origin in this calculation is taken as the geometric stagnation point. The above calculation of $\varepsilon_M$ due to free-stream turbulence was carried out only when the flow was laminar. Otherwise, the analysis would give significantly increased heat transfer for fully turbulent flow (Boyle, 1991). For the cases analyzed here, it implies that Forest’s model is used only for the ACE rotor since for both the VKI rotor and the C3X vane, the flow is turbulent at the leading edge itself due to the shower-head injection.

### 2.2 Crawford’s Model

Crawford’s model for augmentation of eddy viscosity due to film cooling (Crawford et al., 1980) was developed for use in a two-dimensional boundary layer code to predict heat transfer in full-coverage film cooling situations on flat surfaces. Though not really applicable to the situation, it was used by Stepka and Gaugler (1983) to compare the predicted Stanton numbers with the experimental data for rows of film-cooling holes around the circumference of a cylinder in crossflow. In the absence of a better model, we adopted it also for the present calculations. According to this model, the eddy diffusivity for momentum in the presence of film cooling is modeled by algebraically augmenting the Prandtl mixing length using

$$\frac{\ell}{\delta} = (\frac{\ell}{\delta})_{3-D} + (\frac{\ell}{\delta})_{a}$$  \hspace{1cm} (3)

where the “3-D” subscript refers to the 3-D mixing length from the Baldwin and Lomax model, and the “a” denotes the departure due to jet-boundary layer interaction, given by

$$F = 2.718 \left( \frac{\gamma}{PD} \right)^{0.5} \exp \left( \frac{- (\gamma/\delta)^{2}}{2} \right)$$

$$f = \exp \left[ - (x/\delta)^2 \right]$$

$$\lambda_{max,a} = 0.0353 \exp(2.65B_r) \quad \text{for slant angled injection}$$

$$\lambda_{max,a} = 0.0177 \exp(2.64B_r) \quad \text{for compound angled injection}$$

$$\lambda_{max,a} = 0.0601 \exp(3.46B_r) \quad \text{for normal injection}$$

where $x$ is the streamwise distance measured from the point of injection, and PD is the penetration distance. While Crawford’s model is essentially two-dimensional, we extended it to three dimensions by linearly augmenting the eddy viscosity in the spanwise direction between holes.

### 3. BLADES AND EXPERIMENTAL DETAILS

The experimental data on the C3X vane has been provided by Hylton et al. (1988). Figure 1 shows the C3X vane with the film cooling hole details. The test vane was internally cooled by an array of ten radial cooling holes (not shown in Fig. 1) in the active part of the vane. No heat transfer measurements were made in the actual film-cooled nose piece of the vane as it was thermally isolated from the rest of the vane. In addition to the details available in Fig. 1, the two rows of holes on the pressure surface were located at $s/m = 0.197, 0.225$, and on the suction surface at $s/m = 0.254, 0.276$. One row of shower-head holes was located at the geometric leading edge, with one row on the suction side and three on the pressure side. The active part of the test vane surface was instrumented with 123 0.51 mm diameter sheathed CA thermocouples to measure the temperature at the blade surface. The thermocouple junctions were located in a plane 2.54 mm off mid-span. The heat transfer coefficient for each radial cooling hole was calculated from the hole diameter, measured coolant flow rate, and coolant temperature with a correction applied for thermal entry region effects. The internal temperature field of the test vane was obtained from a finite element solution of the steady state heat conduction equation, using the measured surface temperatures as boundary conditions. Experimental values of the heat flux at the blade surface were then obtained from the normal temperature gradient at the blade surface, and these were used to derive the local heat transfer coefficient at a spanwise location 2.54 mm off the mid-span of the blade. More details are available in Hylton et al. (1988).

The experimental data on the VKI rotor has been provided by Camci and Arts (1990), using the short-duration VKI Isentropic Compression Tube facility. Figure 2 shows the VKI rotor geometry along with cooling hole details. Three staggered rows of cylindrical cooling holes ($d = 0.8$ mm; $s/c = -0.0285, 0$, and $0.040$) were located on both the pressure and suction sides of the rotor. The experimental data points were compared with the theoretical predictions of the model. The model was able to predict the heat transfer coefficient for both the VKI rotor and the C3X vane with good accuracy.
0.0285) were located around the leading edge. The row and hole spacings were respectively 2.28 and 2.48 mm. These holes were spanwise angled at 30° from the tangential direction and drilled in a plane perpendicular to the blade surface. Two staggered rows of conical holes (d = 0.8 mm; s/c = 0.206, 0.237) were located on the suction side. The row and hole spacings were respectively 2.48 and 2.64 mm. These holes were inclined at 37° and 43° with respect to the local blade surface and drilled in a plane perpendicular to the span. One row of conical holes (d = 0.8 mm; s/c = -0.315) was located along the pressure side. The hole spacing was 2.64 mm. These holes were inclined at 35° with respect to the local blade surface and drilled in a plane perpendicular to the span. The blade instrumented for heat flux measurements was milled from 'Macor' glass ceramic and 45 platinum thin films were applied on its surface. Three independent cavities were drilled along the blade height to act as plenum chambers. The local wall convective heat flux was deduced from the corresponding time-dependent surface temperature evolution, provided by the platinum thin-film gages. The wall temperature/wall heat flux conversion was obtained from an electrical analogy, simulating a one-dimensional semi-infinite body configuration. More details are available in Camci and Arts (1990).

The experimental data on the ACE rotor has been provided by Norton et al. (1990), using the Isentropic Light Piston Tunnel at Oxford University. The blade profile tested was the mid-height streamline section of a highly loaded, transonic, research turbine rotor. Build X of the ACE rotor, shown in Fig. 3, was used for comparison purposes. In this, one row of cylindrical holes (d = 0.65 mm; s/s_n = 0.7) was located on the suction surface, with a hole spacing of 4d. Two staggered rows of cylindrical holes (d = 0.65 mm; s/s_n = 0.5, 0.56) were located on the pressure surface; with a row and hole spacing of 4d each. All holes were inclined 30° to the local blade surface and drilled in a plane perpendicular to the span. The instrumented blades were manufactured from 'Macor' glass ceramic onto which were placed thin film platinum resistance thermometers and pads. The heat transfer measurement technique is similar to that used by Camci and Arts (1990). More details are available in Norton et al. (1990).

4. COMPUTATIONAL DETAILS

For all the blades, the computational span, shown in Fig. 4, is different from the real span. The ordinate in each part of Fig. 4 denotes the distance along the blade surface in the spanwise direction, while the abscissa denotes the distance along the blade surface in the chordwise direction, both normalized by the blade radius, r. For the VKI rotor, the hole spacing in the span direction was assumed to be 2.56 mm (= 6.4 r) for all holes, representing a deviation of ±3% from the actual values of 2.48 and 2.64 mm. It may be noted that the abscissa in Fig. 4 has breaks so as to accommodate all the rows of holes. The shape and orientation of the hole openings in Fig. 4 is a direct consequence of the angles the holes make with the spanwise or chordwise direction. For all the blades, the pattern of holes shown in Fig. 4 is repeated in the spanwise direction. For the C3X vane and the VKI rotor, periodic boundary conditions are imposed due to shower-head injection, while for the ACE rotor, symmetry conditions are imposed on the ends of the computational span.

Since the hole diameter on all the blades is less than 1 mm, the grid size has to be varied along the blade chord. For computational accuracy, the ratio of two adjacent grid sizes in any direction was kept within 0.76 to 1.3. A periodic C-grid with up to one million grid points was used. For the C3X vane, the grid used was 281x45x81, while for the VKI and ACE rotors, it was 353x53x17 and 313x53x17, respectively, where the first number represents the number of grid points along the main flow direction, the second in the blade-to-blade direction, and the third in the span direction. Normal to the blade surface is the dense viscous grid, with y* < 1 for the first point off the blade surface, following Boyle and Giel (1992). Computations were run on the 8-processor Cray Y-MP supercomputer at the NASA Lewis Research Center, and on the 16-processor C-90 supercomputer at NASA Ames Research Center. The code requires about 60 million words (Mw) of storage and takes about 20 seconds per iteration (full-multigrid) on the C-90 machine for one million grid points. For a given grid the first case requires about 1100 iterations to converge, while subsequent cases for the same grid require about 300 iterations starting with the solution for the previous case.

5. RESULTS AND DISCUSSION

Three experimental cases for the C3X vane, three for the VKI rotor and two for the ACE rotor were analyzed for comparison. The values of various parameters for these cases are given in Table 1. In this table, the derived film cooling parameters are based upon the assumption of one-dimensional compressible flow through the hole. For the C3X vane, cases 44135 and 44155 represent the minimum and maximum blowing ratio, respectively, for the shower-head holes, while the case 44135 represents the warmest coolant. For the VKI rotor, case number is designated by the ratio of coolant mass to the main-flow mass; the main difference between the 3.09% and 3.32% cases being the colder coolant for the latter. For the ACE rotor, case 6115 represents about half the blowing ratio for the case 6109. In all cases except case 6115 for the ACE rotor, the blowing ratio is high (B_r > 1.0).

Figure 5 shows the coolant velocity and temperature profiles at the hole exit, effect of which was studied on the heat transfer coefficient at various blade surfaces. The profiles shown in Fig. 5 are at the centerline through the hole, with the abscissa covering the hole. Clearly, the 1/7th power law profile does not satisfy the zero gradient condition at the centerline. The polynomial profile shown is for V_m = 2.449 = twice the maximum velocity for the 1/7th power law profile, and V_f = 0. It was found, however, that results for the heat transfer coefficient corresponding to the polynomial profile did not change more than -5% for -0.4 ≤ V_r ≤ 0.4.

We now present results for the three blades separately. Figure 6 shows the non-uniform experimentally determined temperature on the C3X vane surface for the three cases. These temperature values were specified as the boundary condition for the blade surface temperature in the code as well. In this and later figures, except Figs. 10-12, s represents the normalized distance along the pressure or suction surface of the blade. Besides the somewhat erratic temperature variation over |s| > 0.25, caused by the internal cooling holes (not shown in Fig. 1) in the active part of the blade, there is a sharp drop in temperature at each end of the insulated portion of the blade (|s| = 0.25).
Figures 7-9 provide the effect of coolant velocity and temperature distribution at the hole exit on the normalized heat transfer coefficient (solid and dash curves) at the blade surface in comparison with experimental data (Hylton et al., 1988), denoted by C, for the cases 44135, 44155 and 44355, respectively, at a spanwise location (near mid-span) where the experimental data was taken. The heat transfer coefficient values in these figures have been normalized with respect to an arbitrary value, \( h_0 = 1135.6 \text{ kW/m}^2\text{K}, \) as per Hylton et al. (1988). There is no data given for about 25% of surface length on either side of the leading edge since this portion contained the plenum chambers for injection of the colder gas and was insulated from the rest of the blade in the experimental tests (cf. Fig. 1). The fluctuations in the data are due to the non-uniform blade surface temperature in the experimental data. The nine short vertical lines near the center-bottom of these figures denote the location of film cooling rows. For all three cases the normalized heat transfer coefficient corresponding to the polynomial profiles of coolant velocity and temperature at the hole exit is about 50-60% higher than that corresponding to the 1/7th power law over most of the suction surface. However, the difference over the pressure surface is only about \( \pm 10\% \) for the case 44135 (Fig. 7), about \( \pm 20\% \) for the case 44155 (Fig. 8), and about \( 35\% \) for the case 44355 (Fig. 9). Also, the 1/7th power law profile results seem to match better with the experimental data than the polynomial profile results for all the cases.

For the C3X vane, we may point out that experimentally, the heat flux on the blade (inner) surface was calculated from a finite element analysis of conduction within the blade, and the heat transfer coefficient was then found by dividing this heat flux by \( (T_s - T_w) \). The present study computes the heat transfer coefficients on the blade (outer) surface from the three-dimensional Navier-Stokes analysis. Also, the uncertainty in the heat transfer coefficient measurement varies from about 10% near \(|s| = 0.3\) to about 22% near \(|s| = 0.95\) (Hylton et al., 1988).

Let us now turn to the comparison of results for the VKI rotor. For this rotor, the blade was specified to be isothermal with \( T_s/T_w = 0.7 \). Figures 10-12 display the effect of coolant velocity and temperature distribution at the hole exit on the normalized heat transfer coefficient (solid and dash curves) at the blade surface in comparison with experimental data (Camci and Arts, 1990), denoted by C, for the three cases at mid-span. In these figures, \( h_s \) corresponds to the heat transfer coefficient at an uncooled blade surface. Also, the abscissa represents the surface distance along the blade normalized by the true chord, in conformity with the available experimental data (Camci and Arts, 1990). The six short vertical lines in the center-bottom of these figures denote the location of film cooling rows. From these figures we find, in contrast to the results for the C3X vane, that the differences in \( h_s/h_0 \) values corresponding to the two coolant profiles at the hole exit are negligible over most of the suction surface and considerable (about 30%) over the pressure surface. The heat transfer coefficient corresponding to the polynomial profiles of coolant injection is generally larger than that corresponding to the 1/7th power law profiles. Also, comparison with experimental data is fair for either of the coolant profiles results. The experimental uncertainty in the measurement of heat transfer coefficient is about 5% except in the shower-head region where it is estimated to be as high as 10-15\% (Camci and Arts, 1990).

Due to normalization with respect to \( h_0 \), however, each experimental data point represents two measurements, one for the cooled and another for the uncooled blade. The same is true for the computations as well, and may be the reason for the relatively good comparison with the experimental data for the VKI rotor in contrast to that for the C3X vane. We may also point out that the suction and pressure surface holes on the VKI rotor are conical while the shower-head holes on the VKI rotor as well as all holes on the C3X vane are cylindrical. This may account for the relatively smaller effect of coolant velocity and temperature distribution at the hole exit on the heat transfer coefficient at the VKI rotor surface in contrast to that for the C3X vane.

We now turn to the discussion of results for the ACE rotor. Figure 13 shows the non-uniform experimentally determined temperature on the ACE rotor surface for the two cases analyzed. These temperature values were specified as the boundary condition for the blade surface temperature in the code as well. Figures 14 and 15 show the effect of coolant velocity and temperature distribution at the hole exit on the heat transfer coefficient (solid and dash curves) at the blade surface in comparison with experimental data (Norton et al., 1990), denoted by C, for the two cases at mid-span. The short vertical lines in these figures as well as Fig. 16 denote the location of film cooling rows. Due to the absence of shower-head cooling, this is the only case where Mayle's transition criterion and Forest's model for augmentation of laminar heat transfer at the leading edge due to free-stream turbulence are useful. Clearly, both models seem to be effective in yielding results that compare well with the experimental data. While the effect of coolant profiles at the hole exit is negligible for the low blowing ratio case 6115 in Fig. 14, it is considerable (as much as 50% higher \( h \) corresponding to the polynomial profile) over the pressure surface for the high blowing ratio case 6109 in Fig. 15. For both cases, however, effect on the suction surface is negligible, in conformity with the results for the VKI rotor but in direct contrast to those for the C3X vane. The polynomial profile for the coolant velocity and temperature distribution at the hole exit results in a very good comparison with the experimental data downstream of the cooling holes on the pressure surface in Fig. 15. Norton et al. (1990) could not get such a good comparison on the pressure surface; their prediction is similar to ours for the 1/7th power law profile.

Figure 16 shows the effect of Crawford's model on the heat transfer coefficient at the ACE rotor surface for the case 6109. The results in Fig. 16 correspond to the polynomial profiles for coolant velocity and temperature at the hole exit. Clearly, the effect of Crawford's model is felt only within the region of holes; it is negligible downstream of the holes. We may note that due to the absence of shower-head cooling, the flow upstream of the holes is essentially two-dimensional (no spanwise variation) for the ACE rotor.

6. CONCLUSIONS

A three-dimensional Navier-Stokes code has been used to study the effect of coolant velocity and temperature distribution at the hole exit on the heat transfer coefficient on three film-cooled turbine blades, namely, the C3X vane, the VKI rotor, and the ACE rotor. Results are also compared with the experimental data for all the blades. Moreover, Mayle's transition criterion (Mayle,
1991), Forest's model for augmentation of leading edge heat transfer due to free-stream turbulence (Forest, 1977), and Crawford's model for augmentation of eddy viscosity due to film cooling (Crawford et al., 1980) are used. It is found that different velocity and temperature distributions of coolant at the hole exit can lead to as much as a 60% change in the heat transfer coefficient at the blade surface in some cases. Also, different effects are observed on the pressure and suction surface depending upon the blade as well as upon the hole shape, conical or cylindrical. Thus specification of proper conditions at the hole exit is important in film-cooling applications. This calls for a detailed analysis of the in-hole and near-hole physics under conditions relevant to the gas turbine.

**Abstract:**
An existing three-dimensional Navier-Stokes code (Arnone et al., 1991), modified to include film cooling considerations (Garg and Gaugler, 1994), has been used to study the effect of coolant velocity and temperature distribution at the hole exit on the heat transfer coefficient on three film-cooled turbine blades, namely, the C3X vane, the VKI rotor, and the ACE rotor. Results are also compared with the experimental data for all the blades. Moreover, Mayle's transition criterion (Mayle, 1991), Forest's model for augmentation of leading edge heat transfer due to freestream turbulence (Forest, 1977), and Crawford's model for augmentation of eddy viscosity due to film cooling (Crawford et al., 1980) are used. Use of Mayle's and Forest's models is relevant only for the ACE rotor due to the absence of showerhead cooling on this rotor. It is found that, in some cases, the effect of distribution of coolant velocity and temperature at the hole exit can be as much as 60% on the heat transfer coefficient at the blade suction surface, and 50% at the pressure surface. Also, different effects are observed on the pressure and suction surface depending upon the blade as well as upon the hole shape, conical or cylindrical.
