THE CAMBRIDGE-CAMBRIDGE X-RAY SERENDIPITY SURVEY. 2: CLASSIFICATION OF X-RAY LUMINOUS GALAXIES (Royal Greenwich Observatory) 12 p
ABSTRACT
We present the results of an intermediate-resolution (1.5Å) spectroscopic study of 17 X-ray luminous narrow emission-line galaxies previously identified in the Cambridge-Cambridge ROSAT Serendipity Survey and the Einstein Extended Medium Sensitivity Survey. Emission-line ratios reveal that the sample is composed of ten Seyfert and seven starburst galaxies. Measured linewidths for the narrow Hα emission lines lie in the range 170 — 460 km s$^{-1}$. Five of the objects show clear evidence for asymmetry in the [OIII]λ5007 emission-line profile. Broad Hα emission is detected in six of the Seyfert galaxies, which range in type from Seyfert 1.5 to 2. Broad Hβ emission is only detected in one Seyfert galaxy. The mean full width at half maximum for the broad lines in the Seyfert galaxies is $\text{FWHM} = 3900 \pm 1750$ km s$^{-1}$. Broad (FWHM = 2200 ± 600 km s$^{-1}$) Hα emission is also detected in three of the starburst galaxies, which could originate from stellar winds or supernovae remnants. The mean Balmer decrement for the sample is $\text{Ha}/\text{Hβ} = 3$, consistent with little or no reddening for the bulk of the sample. There is no evidence for any trend with X-ray luminosity in the ratio of starburst galaxies to Seyfert galaxies. Based on our previous observations, it is therefore likely that both classes of object comprise ~ 10 per cent of the 2 keV X-ray background.

Key words: X-rays: general – galaxies: active – quasars: general

1 INTRODUCTION

A number of recent spectroscopic surveys of soft (0.5—2 keV) X-ray sources detected at faint fluxes with the ROSAT mission (Boyle et al. 1995, Georgantopoulos et al. 1995) have all confirmed that, while QSOs comprise in excess of 50 per cent of the total X-ray population down to these flux levels, an increasingly large number of X-ray luminous, narrow (FWHM < 1000 km s$^{-1}$) emission-line galaxies (NLXGs) are identified as counterparts to faint X-rays sources with fluxes $S(0.5 - 2\text{keV}) < 10^{-13}$ erg s$^{-1}$cm$^{-2}$. These galaxies have X-ray luminosities in the range $10^{42} - 10^{43.5}$ erg s$^{-1}$, over 100 times more luminous than late-type galaxies (Fabbiano 1989), whose low-resolution optical spectra they most closely resemble. In a previous paper in this series (Boyle et al. 1995; hereinafter Paper I), we have demonstrated that, based on their space density and cosmological evolution, these emission-line galaxies could comprise between 15—30 per cent of the soft 0.5—2 keV X-ray background. This is entirely consistent with the upper limit of ~ 50 per cent for the contribution of QSOs to the 0.5—2 keV X-ray background, based on their luminosity function (Boyle et al. 1994), clustering properties (Georgantopoulos et al. 1993) and X-ray spectra (Georgantopoulos et al. 1995).

Unfortunately, due to the poor quality of many of the identification spectra, little is known about the precise nature of this population. In particular, it is not clear whether these emission-line galaxies are examples of starburst galaxies or 'hidden' active galactic nuclei (e.g. Seyfert 2 galaxies), both of which have previously been suggested as possible significant contributors to the X-ray background (Griffiths & Padovani 1990, Fabian & Barcons 1992) and are known to exist in X-ray surveys (e.g. Böler et al. 1992), albeit at much higher X-ray flux levels and lower space densities.

In order to understand the origin of this potentially significant population of X-ray sources, we report in this paper on a detailed intermediate-resolution spectroscopic study of 17 NLXGs, 10 of which have been identified in the Cambridge-Cambridge ROSAT Serendipity Survey (CRSS, see Paper I) and a further 7 objects selected at random from the Einstein Extended Medium Sensitivity Survey (EMSS, Stocke et al. 1991) which we suspect are similar (Paper I). This sample comprises all but two of the NLXG identified in the CRSS (CRSS1514.4+5627 and CRSS1605.9+2554), which were not observed due to lack of time.

In Section 2 we report on the observation and analysis of the NLXG spectra. Based on the results obtained from these spectra, we discuss the properties and classification of the NLXG in Section 3, including the implications for the
composition for the soft X-ray background. We present our conclusions in Section 4.

2 DATA

2.1 Observations

We obtained intermediate-resolution spectra of 17 emission-line galaxies previously identified in the CRSS and EMSS using the ISIS double arm spectrograph at the WHT on the nights of 1994 June 9-10. We operated ISIS with the Tektronix CCD on the blue arm and the EEV CCD on the red arm. We used 600 lines mm\(^{-1}\) gratings in both arms, giving an instrumental resolution of 1.5 Å (0.67 Å pix\(^{-1}\)). For each galaxy, we observed the redshifted H\(\beta\)/[OIII]\(\lambda 5007\) and H\(\alpha\)/[NII]\(\lambda 6717,6731\) regions in the blue and red arms respectively. Throughout the run, conditions were good (1 arcsec seeing) and we observed all objects with a 1.5 arcsec slit. The redshifts of the program objects allowed us to observe the H\(\beta\)/[OIII]\(\lambda 5007\) and H\(\alpha\)/[NII]\(\lambda 6717,6731\) regions in all galaxies with only one change of grating position and dichroic. Details of the observations, including exposure times for each program object, are given in Table 1. A further two emission-line galaxies were observed with ISIS as part of the WHT service observation program on the night of 1994 September 20. The observations were made with the ISIS red arm, EEV detector and the 1200 lines mm\(^{-1}\) grating, giving an overall resolution of 0.7 Å (0.33 Å pix\(^{-1}\)) in the H\(\alpha\)/[NII]\(\lambda 6717,6731\) region. X-ray luminosities in the 0.5–2 keV band and optical magnitudes for all NLXG are also listed in table 1. The V magnitudes listed for the CRSS were obtained from the APM Northern Sky Survey (Irwin, McMahon and Maddox 1994). The optical magnitudes correspond to the total galaxy magnitude and cannot therefore be used as an accurate measure of the nuclear magnitudes for these objects. To derive the X-ray luminosities we assumed \(H_0 = 50\) km s\(^{-1}\) Mpc\(^{-1}\), \(q_0 = 0.5\) and an X-ray spectral slope \(\alpha_X = 1\) (\(f_X \propto \nu^{-\alpha_X}\)). To convert the EMSS 0.3–3.5 keV band luminosities to the 0.5–2.5 keV band we divided by a factor of 1.8, the conversion factor between the Einstein and ROSAT bands for a spectral index \(\alpha_X = 1\) (see Boyle et al. 1995).

2.2 Data Reduction and Analysis

The data were reduced using standard routines in the IRAF reduction package on the Cambridge SPARC cluster. Optimally-extracted galaxy spectra were wavelength-calibrated using copper-argon arc spectra taken throughout each night during the observing run. The spectra were flux-calibrated using spectrophotometric standards taken during evening and morning twilight on each night. We present the reduced spectra for each galaxy in figure 1. The large gap in each spectrum corresponds to the gap in the wavelength coverage between the blue and red arms of ISIS.

Before measuring the emission lines, we first shifted each spectrum to the rest-frame using the redshift given in Table 1 and then divided each spectrum by a second-order polynomial fit to its own continuum, after excluding the regions \(\pm 150\) Å around the H\(\beta\)/[OIII] and H\(\alpha\)/[NII] lines. This division created a flat continuum (advantageous in the line-fitting routine described below) without removing any weak, broad features which may be present in the H\(\alpha\) or H\(\beta\) emission.

‡ Wrong source identified as z = 0.158 AGN in Stocke et al. (1991)
We then used the SPECFIT routine (written by Dr Gerard Kriss) in IRAF to measure emission line ratios, rest equivalent widths (W) and full width at half maximum intensity (FWHM) of the prominent emission lines in the spectra of the galaxies. This routine uses a Marquand $\chi^2$ minimisation routine to fit a user-specified number of functions (power-law or linear continuum, gaussian or logarithmic line profiles) to the input spectrum. In this case, the simplifying step of continuum division allowed us to fix the continuum at a constant value of 1. The fitting process yields typical Poission errors of 15 per cent and 10 per cent in the measurement of the equivalent widths and FWHM respectively.

For each of the 13 spectra in which [OIII]A5007 was observed at a high signal-to-noise ratio (excluding CRSS1406.7+2838 and CRSS1705.3+6049, see Fig. 1), we first used the SPECFIT routine to fit both gaussian and logarithmic profiles to this emission line, in order to establish the correct profile shape to fit to the narrow emission lines. We chose the [OIII]A5007 line for this purpose because it is the strongest narrow line observed in each spectrum which does not have any weak, broad (FWHM > 1000 km s$^{-1}$) component and is not blended with any other lines. We found that, in every case, the $\chi^2$ value for the gaussian profile fit was less than that for the logarithmic profile fit. In 10 cases, the F-ratio test (based on the ratio of the $\chi^2$ statistics, see Mood
& Graybill 1963) implied that the gaussian fit was preferred at the 99 per cent confidence level over the logarithmic fit. Based on this test, we subsequently used gaussian profiles throughout the fitting procedure.

Several of the \([\text{OIII}]_{\lambda 5007}\) emission lines appeared to exhibit a significant blue asymmetry. To quantify this observation, we performed another F-ratio test, this time on the \(\chi^2\) values obtained from fitting a single and double gaussian to the \([\text{OIII}]_{\lambda 5007}\) line. In the latter case, the second gaussian component was blueshifted with respect to the rest wavelength of the line. We also investigated a double gaussian with a redshifted component. We stress that the use of this double gaussian fit is not intended to reflect any physical significance for the origin of any asymmetry. It simply provides us with a simple way to establish the significance of the asymmetry and obtain a more accurate measurement of the equivalent width, while retaining a consistent measurement process with all the other emission lines.

In five cases (~35 per cent of the sample) we found a significant blue asymmetry, with the extra gaussian component improving the preferred fit at the 99 per cent confidence level. No redshifted components were detected at the same level of significance. The NLXG in which the blueshifted components were observed are CRSS1429.0+0120, MS1252.4-0457, MS1414.8-1247, MS1555.1+4522 and MS2044.1+7532. Examples of these

† Whittle (1985) asymmetry parameter, corresponding to the relative wavelength shift between the 10 percentile areas in the blue and red wings of the emission-line profile from the line centre.

asymmetries with the additional fitted components can be seen in figure 2, where we have plotted expanded spectra of the regions surrounding the major emission lines for representative sample of 4 NLXG observed in this survey. The strengths of the additional components range from 25 per cent to 88 per cent of principal line, with velocity shifts between the two fitted components ranging from 210 km s⁻¹ to 653 km s⁻¹ (see table 3). We have confirmed that the summed equivalent width of both fitted components in these asymmetric lines is also good estimate (accurate to within 15 per cent) of the total equivalent width measured without line-fitting.

Similarly asymmetric [OIII]λ5007 profiles have also been seen in active galaxies by Whittle (1985). Whittle identified blue asymmetries in most of the AGN/HII regions he studied. If we use the same asymmetry parameter as defined by Whittle (a(20%)), we find that the five NLXG (out of 13 with measurable [OIII]λ5007) in this analysis which require blueshifted components all have an asymmetry parameter a(20%) > 0.2. In Whittle’s sample approximately 40 per cent of the AGN had asymmetries with a(20%) > 0.2, and so the results found here would appear to be consistent with Whittle’s observations. Based on the Kolmogorov-Smirnoff (KS) test statistic, we find that the overall distribution of the measured [OIII]λ5007 line asymmetries (irrespective of their significance level) for the NLXG sample is consistent at the 95 per cent confidence level with that observed by Whittle (1985). Measured a(20%) values for all [OIII]λ5007 lines are given in table 2. The origin of these asymmetries is still a matter of some debate, but they are most likely to
Figure 2: Expanded spectra of the regions around the prominent emission lines in a representative sample of 4 NLXG observed in our sample. The spectra have been corrected to the rest frame and been divided through by a low-order polynomial fit to the continuum. The accepted fit is denoted by the short dashed line. The contribution of the individual emission lines is shown by the longer dashed lines. (a) CRSS1429.0 + 0120: a starburst galaxy with asymmetric [OIII]/Hβ and [NII]/Ha.

For each spectrum, separate fits were then carried out for the following combination of lines over the wavelength intervals indicated: Hβ/[OIII]λλ4959, 5007 (4800Å - 5070Å); [OII]λ6300 (6280Å - 6320Å); [NI]λ6549/Hα/[NII]λ6584 (6440Å - 6690Å); [SII] λλ6717, 6734 (6697Å - 6754Å). For each narrow emission line we tried two fits; a single narrow (FWHM < 1000 km s⁻¹) gaussian, and two narrow gaussians with an additional blueshifted component. For the Balmer lines we also tried a fit which comprised a narrow plus broad (FWHM > 1000 km s⁻¹) gaussian profile. To improve the robustness of the fits, we made every attempt to minimize the number of free parameters in each fit. As discussed above, the continuum-divided spectra first allowed us to fix the continuum at a constant value of 1. We also fixed the [NII]λ6734:λ6717 emission line ra-
ratio at 3.01:1 and the [OIII]λ5007:λ4959 emission line ratio at 2.88:1. Similarly, we fixed the relative rest wavelength ratios of the [NII], [SII] and [OIII] emission line pairs at 6549:6584, 6717:6734 and 4959:5007 respectively. Finally, for each group of narrow lines fitted simultaneously (i.e. Hβ/[OIII]λλ4959,5007, [NII]λ6549/Hα/[NII]λ6584 and [SII] λλ6717,6734), we adopted a single value for the FWHM of the narrow gaussian component fitted to all lines.

For each set of fits (narrow only, narrow plus blueshifted component, narrow plus broad) we again used the F-ratio test to discriminate between them, accepting the more complex fit (i.e. including the blueshifted or broad components) where it was preferred to the narrow-line-only fit at greater than 99 per cent confidence level.

3 RESULTS

Based on the fitting procedure outlined in the previous section, the measured rest-frame emission line equivalent widths and FWHM for each AGN are listed in table 2. For each object the data is presented in two lines; the first provides the information for the narrow lines and the second lists the measured parameters for the second component (blueshifted line or broad emission line), if present. The identification of each component (narrow, blueshifted or broad) is given at the end of each line. Expanded spectra
of the emission line regions in 4 representative NLXG are plotted in figure 2. In each spectrum the total fit is shown by the short dashed line with the individual emission lines components represented by long dashed lines. The principal narrow emission line ratios, together with the velocity shift ($\Delta u$) of any blueshifted [OIII]$\lambda$5007 lines observed, are given in table 3. The emission line ratios quoted in table 3 (and used throughout the following discussion) are ratios of the total narrow emission-line equivalent widths (i.e. including both components of any 'double gaussian') and not intensity ratios. For the Balmer line ratios, the subscripts in table 3 refer to the ratio of the narrow (1) or broad (2) components. Similarly, the subscripts on the [OIII]$\lambda$5007 line ratios in table 3 correspond to the rest (1) and blueshifted (2) components respectively. For a power-law continuum $f_\nu \propto \nu^{-\alpha}$ it can be shown straightforwardly (see Boyle 1990) that the ratio of equivalent widths $W_1$ and $W_2$, measured at $\lambda_1$ and $\lambda_2$ respectively correspond to a ratio of intensities $I_1$ and $I_2$:

$$\frac{I_1}{I_2} = \frac{W_1}{W_2} \left( \frac{\lambda_2}{\lambda_1} \right)^{2-\alpha}$$

With the exception of the Hα/Hβ line ratio (discussed separately below), the correction from equivalent width ratio to intensity ratio is negligible for all line ratios quoted in table 3 (e.g. < 4 per cent in the [OIII]/Hβ ratio) for most realistic
values of the continuum slopes, $\alpha \sim 0.5$.

In table 3 we also list the classification assigned to each NLXG on the basis of its position in the \([\text{NII}]\lambda 6584/\text{H}$ \(\alpha\) vs (see figure 3) using the scheme of Baldwin, Philips and Terlevich (1981). From figure 3, we can see that there is a good separation between the objects with HII-like spectra (i.e. starburst galaxies) and AGN-like spectra (Seyferts 1.5-2). The values of the other emission line ratios e.g. \(\text{H}\alpha/\text{[OII]}\lambda 6300\) and \(\text{H}\alpha/\text{[SII]}\lambda 6717 + 6734\) in each NLXG are also consistent with the classification based on this diagram. For two NLXGs we have no observations of the \(\text{H}\beta/\text{[OIII]}\lambda 5007\) region. The large value of the \(\text{H}\alpha/\text{[OII]}\lambda 6300\) and \(\text{H}\alpha/\text{[SII]}\lambda 6717 + 6734\) ratios in CRSS0009.0+2041 mean that this object is likely to have an HII-like spectrum, whereas the much lower \(\text{H}\alpha/\text{[OII]}\lambda 6300\) ratio in CRSS0009.7+2629 implies an AGN-like spectrum (see Filippenko & Terlevich 1992). Although only the \([\text{OIII]}\lambda 5007\) line is reliably detected in CRSS1705.3+6049 the upper limit of the equivalent width of the much weaker \(\text{H}\beta\) suggests that this object is also likely to be an AGN, although this classification is still rather uncertain. For each object identified as an AGN, we further classified the object as a Seyfert 1.5, 1.8, 1.9 or 2, based on the relative strengths of the broad and narrow \(\text{H}\alpha\) components using the approximate relation given by Netzer (1990): $1 + (\text{Narrow}/\text{Total})^{0.4}$.
Based on the observed emission line ratios in the 17 NLXGs observed, we have identified 7 starburst galaxies and 10 AGN (including 5 Sy 1.5, 4 Sy 1.8-2 galaxies and one uncertain classification). We found no LINERS (see Heckman 1980) in the NLXG sample. These results are broadly in agreement with the results of Fruscione, Griffiths and MacKenty (1993), who found similar numbers of starburst galaxies and Seyfert galaxies amongst a similar sample of EMSS 'ambiguous' sources. Using the KS test, we were able to determine that there is no significant difference in the relative numbers of starburst galaxies/AGN found in the CRSS and EMSS samples.

The AGN and the starbursts cannot be distinguished in the present small sample by X-ray luminosity, redshift, optical magnitude, presence of a broad component, or line asymmetry. There is also no evidence for any X-ray luminosity dependence in the ratio of starburst galaxies to AGN. The X-ray to optical ratio \(a_{ox}\) might be able to discriminate, since nearby starbursts are relatively X-ray faint (Fabbiano 1989), but the large galaxy contribution to the optical luminosity dependence in the ratio of starburst galaxies to AGN. The X-ray to optical ratio \(a_{ox}\) might be able to discriminate, since nearby starbursts are relatively X-ray faint (Fabbiano 1989), but the large galaxy contribution to the optical luminosity dependence in the ratio of starburst galaxies to AGN.

Based on the observed emission lines $\lambda$ 1424, 1500, 4959, 5100, 6548, 6584, 7699 and 8446 Å, 17 starburst galaxies and 10 AGN have been classified. Nine NLXGs observed, we have identified 7 starburst galaxies, including 5 Sy 1.5, 4 Sy 1.8-2 galaxies and one uncertain classification. We found no LINERS (see Heckman 1980) in the NLXG sample. These results are broadly in agreement with the results of Fruscione, Griffiths and MacKenty (1993), who found similar numbers of starburst galaxies and Seyfert galaxies amongst a similar sample of EMSS 'ambiguous' sources. Using the KS test, we were able to determine that there is no significant difference in the relative numbers of starburst galaxies/AGN found in the CRSS and EMSS samples.

The AGN and the starbursts cannot be distinguished in the present small sample by X-ray luminosity, redshift, optical magnitude, presence of a broad component, or line asymmetry. There is also no evidence for any X-ray luminosity dependence in the ratio of starburst galaxies to AGN. The X-ray to optical ratio \(a_{ox}\) might be able to discriminate, since nearby starbursts are relatively X-ray faint (Fabbiano 1989), but the large galaxy contribution to the optical luminosity dependence in the ratio of starburst galaxies to AGN.

The AGN and the starbursts cannot be distinguished in the present small sample by X-ray luminosity, redshift, optical magnitude, presence of a broad component, or line asymmetry. There is also no evidence for any X-ray luminosity dependence in the ratio of starburst galaxies to AGN. The X-ray to optical ratio \(a_{ox}\) might be able to discriminate, since nearby starbursts are relatively X-ray faint (Fabbiano 1989), but the large galaxy contribution to the optical luminosity dependence in the ratio of starburst galaxies to AGN.
Figure 3 [NII]λ6584/Hα − [OIII]λ5007/Hβ emission-line ratio diagram for the NLXGs observed in this paper. CRSS objects are indicated by the filled circles and EMSS objects by the open circles. The division between AGN-like and HII-like spectra (dotted line) is based on the criterion of Baldwin, Philips & Terlevich (1981).

the derivation of these narrow-line ratios (dominated by the ∼ 15 per cent uncertainty in the equivalent width measurement of each individual line), this is not a significant discrepancy. The lack of significant reddening from the observed Hα/Hβ ratios is also consistent with the results from the X-ray spectral analysis (Ciliegi et al. 1995) in which none of the NLXG X-ray spectra (with the exception of CRSS1412.5+4355) show any evidence for any intrinsic absorption due to neutral hydrogen in excess of the galactic value (although few NLXG have sufficient X-ray counts to permit a detailed spectral fit). The Seyfert 1.8 galaxy CRSS1412.5+4355 has an intrinsic neutral hydrogen X-ray column density $N_H = 2.5 \pm 1.0 \times 10^{20}$ cm$^{-2}$, corresponding (for galactic gas-to-dust ratios) to a visual extinction of $A_V = 0.14$ mag (Zombeck 1990). This small amount of extinction is consistent with the mild amount of reddening implied by the intensity ratio $H\alpha/H\beta = 3.3$ derived for CRSS1412.5+4355. Thus, while individual NLXG may exhibit some reddening, it would appear that significant obscuration is not a general feature of either the starburst or Seyfert population in this sample.
As demonstrated in Paper I, the NLXG sample comprises between 15-35 per cent of the soft (2 keV) X-ray background. With an approximate ratio of 10:7 AGN:starbursts identified in this paper, this suggests that the approximate contributions of the two populations also lie in the approximate ratio 10:7 per cent. However, the numbers of NLXGs identified are still small, and we can not rule out equal contributions from both classes of object. Given the composition of the NLXG sample, it is not surprising that the rate of cosmological evolution derived in Paper I, \( L_X \propto (1 + z)^{2.6\pm 1} \), is so similar to that of QSOs \( (L_X \propto (1 + z)^{3.0\pm 0.2}) \). Unified models of AGN (in which the appearance of an object as a Seyfert 1 or 2 is merely dependent on viewing angle) naturally imply that Seyfert 2s (or similar types) must evolve at the same rate as Seyfert 1s/QSOs. In addition, it is also known that starburst galaxies also undergo a rate of cosmological evolution in infra-red luminosity \( L_{IR} \propto (1 + z)^{3.0\pm 1.0} \) (Saunders et al. 1990) which is consistent with that of QSOs in the optical and X-ray regimes (see Boyle 1993).

4 CONCLUSIONS

We have obtained intermediate-resolution spectra of 17 NLXG identified from the CRSS and EMSS samples. Based on their emission line ratios, we estimate that the sample contains 7 starburst galaxies and 10 Seyfert galaxies. Six of the Seyfert galaxies show evidence for broad H\( \alpha \) emission, although only one conclusively exhibits broad H\( \beta \) emission. The Seyfert types range from Seyfert 1.5 to 2. In addition, 3 of the starburst galaxies exhibit evidence for weak broad \( (\sim 2000 \text{ km s}^{-1}) \) H\( \alpha \) emission. Thus, the NLXG sample as originally identified in Paper I appears to be a heterogeneous mix of Seyfert and starbursts. Only the line ratios distinguish the two classes. In all other characteristics they share similar properties (z, optical magnitude, \( L_X \), and line asymmetry distributions). If the two classes are powered by different processes this is surprising. Further discriminants need to be searched for in larger samples. Both classes contribute approximately equally to the 2 keV X-ray background at a level of between 7 and 17 per cent.

ACKNOWLEDGEMENTS

RGM acknowledges the receipt of a Royal Society University Research Fellowship. We are indebted to Dr Mike Irwin for observing the two spectra obtained during spectroscopic service time on the William Herschel Telescope. We also would also like to thank Dr Gerard Kriss for providing help with the SPECFIT routine. BJB acknowledges the support and hospitality of the Smithsonian Astrophysical Observatory. The X-ray data was obtained from the Leicester and Goddard ROSAT archives. This work was partially supported by NASA grants NAGW-2201 (LTSA) and NAS5-30934 (RSDC). The optical spectra were obtained at the William Herschel Telescope at the Observatory of the Roque de los Muchachos operated by the Royal Greenwich Observatory.
