ABSTRACT

Many analysis algorithms for high-dimensional remote sensing data require that the remotely sensed radiance spectra be transformed to approximate reflectance to allow comparison with a library of laboratory reflectance spectra. In maximum likelihood classification, however, the remotely sensed spectra are compared to training samples, thus a transformation to reflectance may or may not be helpful. The effect of several radiance-to-reflectance transformations on maximum likelihood classification accuracy is investigated in this paper. We show that the empirical line approach, LOWTRAN7, flat-field correction, single spectrum method, and internal average reflectance are all non-singular affine transformations, and that non-singular affine transformations have no effect on discriminant analysis feature extraction and maximum likelihood classification accuracy. (An affine transformation is a linear transformation with an optional offset.) Since the Atmosphere Removal Program (ATREM) and the log residue method are not affine transformations, experiments with Airborne Visible/Infrared Imaging Spectrometer (AVIRIS) data were conducted to determine the effect of these transformations on maximum likelihood classification accuracy. The average classification accuracy of the data transformed by ATREM and the log residue method was slightly less than the accuracy of the original radiance data. Since the radiance-to-reflectance transformations allow direct comparison of remotely sensed spectra with laboratory reflectance spectra, they can be quite useful in labeling the training samples required by maximum likelihood classification. Therefore, each of these transformations from the original radiance data x, to the estimate of reflectance y, can be written as

\[ y = ATx + B \]

where A is a diagonal matrix whose elements are the scale factors for each band, and B is a vector of the offsets for each band. Since the determinant of a diagonal matrix is the product of the diagonal elements, the determinant of A will be non-zero if all the scale factors are non-zero, which implies that A is non-singular. Thus the empirical line approach, LOWTRAN7, flat-field correction, single spectrum method, and internal average reflectance are non-singular affine transformations.

GAUSSIAN MAXIMUM LIKELIHOOD CLASSIFICATION

Next we show that non-singular affine transformations have no effect on Gaussian maximum likelihood classification. The decision rule in this case is to label the sample x as class j if the density of class j has the highest likelihood value of any of the classes: Choose \( o_j \) if \( \arg \max \{ p_o(x|o_j) \} = j \)

where \( p_o(x|o_j) = \frac{1}{\sqrt{2\pi}^n |\Sigma_j|} \exp \left( \frac{-1}{2} (x - m_j)^T \Sigma_j^{-1} (x - m_j) \right) \)

\( m_j \) is the mean vector of class i, and \( \Sigma_j \) is the covariance matrix of class i. Suppose a non-singular affine transformation is applied to the data: \( y = ATx + B \). The mean vector of class i in the transformed data y is \( m_{yi} = ATm_i + B \), the covariance matrix is \( \Sigma_{yi} = AT\Sigma_i A^T \), and the density is

\[ p_o(y|o_j) = \frac{1}{\sqrt{2\pi}^n |\Sigma_{yi}|} \exp \left( \frac{-1}{2} (y - m_{yi})^T \Sigma_{yi}^{-1} (y - m_{yi}) \right) \]

\[ = \frac{1}{\sqrt{2\pi}^n |A^T\Sigma_i A|} \exp \left( \frac{-1}{2} (ATx + B - ATm_i - B)^T \right) \]

\[ = \frac{1}{\sqrt{2\pi}^n |A^T\Sigma_i A|} \exp \left( \frac{-1}{2} (ATx - ATm_i)^T \right) \]

\[ = \frac{1}{\sqrt{2\pi}^n |\Sigma_{yi}|} \exp \left( \frac{-1}{2} (x - m_i)^T \Sigma_i^{-1} (x - m_i) \right) \]

\[ = \frac{1}{\sqrt{|A^T|}} p_o(x|o_j) \]

Note that the value of the density of the transformed data y is simply the value of density of the original data x divided by a positive number. Since the density of each class is divided by the same positive number, the class with the largest likelihood value in the original data x will also have the largest likelihood value in the transformed data y. Therefore the classification of the vector x and y is the same, which implies that a non-singular affine

NON-SINGULAR AFFINE TRANSFORMATIONS

Let x be an n by 1 vector containing the spectral measurements of a pixel. A non-singular affine transformation is any function of the data that can be written in the form

\[ y = ATx + B \]

where A is a constant, non-singular n by n matrix, and B is an optional, constant n by 1 vector.

In the empirical line approach, LOWTRAN7, flat-field correction, single spectrum method, and internal average reflectance, the data in each spectral band is multiplied by a scale factor and in some cases shifted by a constant offset. The same scale factor and offset are used for every pixel in the scene. Therefore, each of these transformations from the original radiance data x, to the estimate of reflectance y, can be written as

\[ y = ATx + B \]

where A is a diagonal matrix whose elements are the scale factors for each band, and B is a vector of the offsets for each band. Since the determinant of a diagonal matrix is the product of the diagonal elements, the determinant of A will be non-zero if all the scale factors are non-zero, which implies that A is non-singular. Thus the empirical line approach, LOWTRAN7, flat-field correction, single spectrum method, and internal average reflectance are non-singular affine transformations.
transformation has no effect on the results of the classification.

**DISCRIMINANT ANALYSIS**

Discriminant analysis (Fukunaga, 1990) is a feature extraction method that finds a linear combination of the original features that maximizes the separation of the classes. Next we show that if the original data is changed by a non-singular affine transformation, the discriminant vectors will also be changed by a non-singular affine transformation. Therefore, if the discriminant vectors are classified using a Gaussian maximum likelihood classifier, it will make no difference whether the original data or the transformed data is used.

Let \( L \) be the number of classes and \( p_i \) be the a priori probability that class \( i \) will occur. The global mean is defined as

\[
\mu_o = \sum_{i=1}^{L} p_i \mu_i,
\]

and the within-class covariance matrix is defined as

\[
\Sigma_{wb} = \sum_{i=1}^{L} p_i (m_i - \mu_o)(m_i - \mu_o)^T.
\]

The discriminant vectors are defined as \( z_x = (x - \mu_o)^T \Sigma_{wb}^{-1} \), whose columns are the \( L-1 \) eigenvectors. Each eigenvalue \( \lambda_i \) is defined as

\[
\lambda_i = (\mu_i - \mu_o)^T \Sigma_{wb}^{-1} (\mu_i - \mu_o).
\]

Since the rank of \( \Sigma_{wb} \) is \( L-1 \), there are \( L-1 \) eigenvectors whose eigenvalues are non-zero. Let

\[
\Phi_x = \begin{bmatrix} e_{x1} e_{x2} & \ldots & e_{x(L-1)} \end{bmatrix}
\]

be a matrix whose columns are the \( L-1 \) eigenvectors. The \( L-1 \) by \( 1 \) matrix whose columns are the \( L-1 \) eigenvectors is selected with real

\[
e_{xi} = \Lambda_i^{-1} e_{xi}.
\]

The eigenvectors and eigenvalues satisfy

\[
(\Sigma_{wb}^{-1} - \lambda_i I) e_i = 0.
\]

Next consider the effect of a non-singular affine transformation \( y = A^T x + b \). Using the transformed data, the covariance matrix is defined as

\[
\Sigma_{yw} = \sum_{i=1}^{L} p_i \Sigma_{wi}.
\]

The eigenvectors and eigenvalues satisfy

\[
(A^T \Sigma_{wb} A - \lambda_i I) e_i = 0.
\]

\[
(A^T \Sigma_{wb} A - \lambda_i I) \Lambda e_i = 0.
\]

\[
(A^T \Sigma_{wb} A - \lambda_i I) \Lambda e_i = 0.
\]

Comparing equations (1) and (2), we see that the affine transformation did not change the eigenvalues: \( \lambda_y = \lambda_x \). Also, each eigenvector from the transformed data is a simple function of the eigenvector from the original data: \( e_{yi} = A^{-1} e_{xi} \). Let

\[
\Phi_y = \begin{bmatrix} e_{y1} e_{y2} & \ldots & e_{y(L-1)} \end{bmatrix}
\]

be a matrix whose columns are the eigenvectors. The discriminant vectors of the transformed data are

\[
z_y = \Phi_y^T \mu_y = \begin{bmatrix} A^{-1} e_{x1} & A^{-1} e_{x2} & \ldots & A^{-1} e_{x(L-1)} \end{bmatrix}^T (A^T x + b)
\]

\[
= \begin{bmatrix} A^{-1} e_{x1} e_{x2} e_{x(L-1)} \end{bmatrix}^T (A^T x + b)
\]

\[
= \begin{bmatrix} e_{x1} e_{x2} \ldots e_{x(L-1)} \end{bmatrix}^T (A^{-1})^T (A^T x + b)
\]

\[
= \begin{bmatrix} \Phi_x^T (A^{-1})^T \end{bmatrix} B
\]

\[
= z_x + \Phi_x^T (A^{-1})^T B
\]

Note that the discriminant vectors of the transformed data \( z_y \) are simply the discriminant vectors of the original data \( z_x \) plus a constant offset. Since adding a constant offset is a non-singular affine transformation (where \( A = I \)), the Gaussian maximum likelihood classification of the discriminant vectors will be the same regardless of whether the original data or the transformed data is used.

**EXPERIMENTS USING ATREM AND LOG RESIDUE**

In the ATREM and log residue methods, the transformation is not constant across the scene. For example in ATREM, the amount of water vapor in each pixel is estimated from the values of the data near the water absorption bands, and this estimate is used in the transformation of that pixel. In the log residue method, each pixel spectrum is divided by the spectral average of that pixel. Since the transformation for each pixel depends on the value of the pixel, these transformations are not affine and, so they may or may not effect classification accuracy.

In order to evaluate the effect of the ATREM and log residue transforms on classification accuracy, experiments were performed with real AVIRIS data. Pixels whose class was known were selected from the radiance data. A certain percentage (12.5, 25, 50%) of these pixels were selected at random to be training samples, and the rest were used as test samples. The training samples were used to compute the discriminant eigenvectors and to train a Gaussian maximum likelihood classifier. The discriminant vectors were extracted from the test samples and classified. The average classification accuracy for 10 trials using random training sets was computed. Then the whole experiment was repeated using the reflectance data and identical training sets. The details of each experiment and the average classification accuracy are presented below.

**Effect Of ATREM On Classification Accuracy**

Experiments were performed with ATREM data from two sites: Jasper Ridge, California, and Tippecanoe County, Indiana. The 1992 AVIRIS radiance data taken over Japer Ridge was converted to reflectance using the ATREM program. Classes from this site were identified by comparing the scenes to a ground cover map made from aerial photographs (Gammon et al., 1993). In all, 3207 pixels were selected from the following classes: evergreen woodland, serpentine grassland, greenstone grassland, deciduous woodland, chaparral, and water. The 193 spectral bands (0.40-1.34, 1.43-1.80, and 1.95-2.47 μm) outside the water absorption bands were used, and the average classification accuracy using 12.5, 25, and 50% of the pixels for training samples is shown in Figure 1. Note that in the trials, the average classification accuracy was slightly lower for the ATREM data than for the original radiance data.

![Figure 1](image-url)
The 1992 AVIRIS scene taken over Tippecanoe County, Indiana was also processed using the ATREM program. Ground observations were used to identify a total of 2521 pixels from the original radiance data (see Figure 4). This improvement did not occur, however, when the other classes and the other bands were used.

When only the 4 classes which were identified using the log residue method and the 31 bands (2.05-2.35µm) surrounding the absorption features of these minerals were used, the average accuracy of the log residue data was slightly higher than that of the original radiance data (see Figure 4). This improvement did not occur, however, when the other classes and the other bands were used.

**SIMILARITY OF CLASSIFICATIONS**

Another experiment was performed with each of the three scenes to measure how many pixels would be classified differently when the reflectance data was used instead of the radiance data. In this experiment, all the samples of known class were used to train a Gaussian maximum likelihood classifier, and a large portion of the scene was classified. The percentage of pixels whose classification differed between the radiance classification and the reflectance classification was 2.7% (Jasper Ridge), 8.4% (Tippecanoe County), and 5.6% (Cuprite).

**CONCLUSION**

Although an estimate of the reflectance of a pixel can be quite useful in labeling training samples for a maximum likelihood classifier, it matters little if the actual classification is performed on the original radiance data or data that has been transformed to approximate reflectance. This result suggests that Gaussian maximum likelihood classification is insensitive to the variations caused by the solar curve and the atmosphere, so that attempts to correct for these changes are unnecessary.
