I. INTRODUCTION AND SUMMARY

Radio absorptivity data for planetary atmospheres obtained from spacecraft radio occultation experiments and earth-based radio astronomical observations can be used to infer abundances of microwave absorbing constituents in those atmospheres, as long as reliable information regarding the microwave absorbing properties of potential constituents is available. The use of theoretically-derived microwave absorption properties for such atmospheric constituents, or using laboratory measurements of such properties under environmental conditions which are significantly different than those of the planetary atmosphere being studied, often leads to significant misinterpretation of available opacity data. Laboratory measurements completed under this grant (NAGW-533), have shown that the opacity from, SO$_2$ under simulated Venus conditions is best described by a different lineshape than was previously used in theoretical predictions. The recognition of the need to make such laboratory measurements of simulated planetary atmospheres over a range of temperatures and pressures which correspond to the altitudes probed by both radio occultation experiments and radio astronomical observations, and over a range of frequencies which correspond to those used in both radio occultation experiments and radio astronomical observations, has led to the development of a facility at Georgia Tech which is capable of making such measurements. It has been the goal of this investigation to conduct such measurements and to apply the results to a wide range of planetary observations, both spacecraft and earth-based, in order to determine the identity and abundance profiles of constituents in those planetary atmospheres.

II. PROGRESS REPORT

This project represents an ongoing activity (since February 1984) to conduct laboratory measurements of the microwave and millimeter-wave properties of simulated planetary atmospheres, in support of NASA missions and ground-based microwave and millimeter-wave observations of planetary atmospheres. The project has also included application of the laboratory results to data from missions and earth-based observations, as well as direct involvement in mission-based microwave measurements (e.g., Magellan atmospheric radio occultation studies) and earth-based measurements (e.g., mapping of Venus with the NRAO/VLA). A renewal project for FY97 funding for this project (November 1, 1996 through October 31, 1997) was submitted to the NASA Planetary Atmospheres Program in July 1996, and has been selected for funding in FY 1997. However, due to the imminent transfer of the grants office at NASA Headquarters, the renewal will be in the form of a new grant issued from the NASA Goddard Space Flight Center, hence, the submission of the Final Report for this grant (NAGW-533).

The technical progress of this project has been described in 22 Progress/Status Reports submitted since 1984. Copies of all reports are available through the NASA Center for AeroSpace Information (NASA-CASI) and are on file at the Planetary Atmospheres Program Office. The current technical status of the project is described in the recent Renewal Proposal and Progress Report #22, which is attached as Appendix A.
III. Students Supported

Over the course of this project, numerous students have been supported as graduate and undergraduate research assistants (see Table I). Additionally, a significant number of student projects, conducted for academic credit, were completed. Nearly every student was involved in the publication of papers in either refereed journals or at conferences, such as AAS/DPS. (See Section IV.) Of the seven Ph.D. students supported by this grant, two have gone on to permanent research positions in planetary and space sciences. Three others have gone to permanent positions in earth atmospheric remote sensing, and two more have taken (or will take) industry positions in space telecommunications. Titles of the Ph.D. dissertations are included in Section IV. of this report.

V. CONCLUSION

Over the 13-year duration of this grant, an effective program integrating microwave and millimeter-wave laboratory measurements with observations conducted from spacecraft experiments and earth-based radio astronomical observations has been conducted. Substantial new results regarding the nature and distribution of tropospheric constituents in the atmospheres of Venus and the outer planets have been obtained. This work was acknowledged by the presentation of the 1996 IEEE Judith A. Resnik Award to the Principal Investigator with the citation, "for contributions to an understanding of the Venus atmosphere through innovative microwave measurements". Similar successes in analysis of the outer planets have also been achieved such as those described in our most recent paper, attached as Appendix B (DeBoer and Steffes, ICARUS, vol. 123, pp. 324-335, October 1996). It is expected that these successes will continue as our new grant from NASA/GSFC commences.

I. INTRODUCTION AND SUMMARY

Radio absorptivity data for planetary atmospheres obtained from spacecraft radio occultation experiments and earth-based radio astronomical observations can be used to infer abundances of microwave absorbing constituents in those atmospheres, as long as reliable information regarding the microwave absorbing properties of potential constituents is available. The use of theoretically-derived microwave absorption properties for such atmospheric constituents, or using laboratory measurements of such properties under environmental conditions which are significantly different than those of the planetary atmosphere being studied, often leads to significant misinterpretation of available opacity data. For example, laboratory measurements completed recently by Suleiman et al. (1996 reprints previously mailed) under this grant (NAGW-533), have shown that the opacity from, SO$_2$ under simulated Venus conditions is best described by a different lineshape than was previously used in theoretical predictions. The recognition of the need to make such laboratory measurements of simulated planetary atmospheres over a range of temperatures and pressures which correspond to the altitudes probed by both radio occultation experiments and radio astronomical observations, and over a range of frequencies which correspond to those used in both radio occultation experiments and radio astronomical observations, has led to the development of a facility at Georgia Tech which is capable of making such measurements. It has been the goal of this investigation to conduct such measurements and to apply the results to a wide range of planetary observations, both spacecraft and earth-based, in order to determine the identity and abundance profiles of constituents in those planetary atmospheres.

II. PROGRESS REPORT

A. Laboratory Measurements under Simulated Venus Conditions

Over the past five years, we have been active in using the Magellan spacecraft to probe the Venus atmosphere by way of radio occultation studies. One key aspect of the Magellan radio occultation results is the high percentage accuracy of the measured profiles of 13 cm and 3.6 cm absorptivity, typically ±10-15%. To take advantage of these new profiles, so as to develop highly accurate abundance profiles of the microwave absorbing constituents, one must know the microwave absorbing and refracting properties of the constituents very accurately. Carbon dioxide (CO$_2$) is only a minor contributor to the microwave absorption at both wavelengths, but its absorption properties are well understood (Ho et al., 1966); and since its abundance does not vary significantly in the Venus atmosphere, its effects can be directly subtracted. At 13 cm, the remaining opacity is almost all due to gaseous sulfuric acid (H$_2$SO$_4$). Sulfuric acid is, of course, the predominant constituent in the Venus clouds. Understanding the spatial and temporal variations in its gas-phase abundance gives insight into the dynamical processes which affect cloud formation, as well as into the thermochemical processes which constrain the abundances of other reactive constituents in the Venus atmosphere such as COS, H$_2$O, CO, SO$_2$, and SO$_3$. While significant headway has been made in developing a theoretically-derived line catalog of the microwave resonances of H$_2$SO$_4$ (see Poynter et al., 1994), large uncertainties in the broadening parameters of the 55,563 microwave lines makes estimates of their combined opacity at 13 cm highly uncertain (~ factor of two).
The best laboratory characterization of the 13 cm opacity from gaseous H$_2$SO$_4$ was conducted under this grant in 1984. (Steffes, 1985) The measurements had accuracies of ±50% which far exceeded the accuracies of the opacity data at that time, and dramatically reduced the uncertainties (± factor-of-seven) of previous estimates of gaseous H$_2$SO$_4$ opacity. However, now that much better measurements of Venus atmospheric absorptivity have been made, better laboratory measurements are necessary.

In the currently completed grant year (November 1, 1995 - October 31, 1996), we have begun a program to more accurately characterize the microwave absorption properties of sulfuric acid vapor (H$_2$SO$_4$) in a CO$_2$ atmosphere. The approach used in measuring the microwave absorptivity of gaseous H$_2$SO$_4$ in a CO$_2$ atmosphere is similar to those previously used by Suleiman et al. (1996) for the absorptivity of SO$_2$ in a CO$_2$ atmosphere under simulated Venus conditions, except that a flask of liquid H$_2$SO$_4$ is used to generate the H$_2$SO$_4$ vapor, when heated. As can be seen in Figure 1, the absorptivity of the gas mixture is measured by observing the effects of the introduced gas mixture on the Q, or quality factor, of the particular resonances of the two resonators contained in the pressure vessel. The changes in the Q are monitored by the computer-controlled spectrum analysis system, since Q is simply the ratio of the resonant frequency to the half-power bandwidth. Note also that changes in the resonant frequencies themselves are related to the refractivities of the gas mixture at those resonant frequencies, and is likewise important information for the proper interpretation of radio occultation data.

As in our previous work with gaseous H$_2$SO$_4$ (Steffes, 1985, 1986), we create a CO$_2$ / H$_2$SO$_4$ mixture by first loading a precisely known volume of liquid H$_2$SO$_4$ into the sample flask and then heating the temperature chamber containing the pressure vessel and flask to a high operating temperature (~560K). This assures a large mixing ratio, since it is the vapor which evaporates from the liquid H$_2$SO$_4$ which will form part of the mixture. In past experiments, one large source of uncertainty rose from potential changes in the H$_2$SO$_4$ mixing ratio caused by reactions with the silver plating on the resonators, which made determination of the actual amount of sulfuric acid vapor difficult. In the new experiments, we have used gold-plated resonators, thus eliminating the effects of reactions.

In Figure 2, the results from the initial absorptivity measurements are shown. These absorptivities are normalized by the sulfuric acid mixing ratio in a CO$_2$ atmosphere. Additional measurements will be completed by August 1996, so as to develop the most accurate formalism for H$_2$SO$_4$ opacity.

B. Venus Observations and Radiative Transfer Modelling

In October 1995, a proposal was submitted to the National Radio Astronomy Observatory (NRAO) for use of the Very Large Array (VLA) for mapping the 1.3 cm and 2 cm emission from Venus. (See Appendix A.) These wavelengths were chosen since they are especially sensitive to the opacity from SO$_2$ (1.3 cm) and H$_2$SO$_4$ (2 cm). (See Suleiman et al., 1996 and Kolodner and Steffes, 1995.) The observations were conducted on April 5, 1996 by graduate students Shady H. Suleiman and Marc A. Kolodner, assisted by Dr. Brian Butler from NRAO. Initial inspection of the maps derived from these observations (See Figures 3 and 4) show darkened regions at latitudes greater than 60 degrees. These darkened regions are larger and more pronounced than simple "limb darkened" zones expected from a uniform disk. They are consistent with the polar darkening observed by the Pioneer Venus
Fig. 1: Block diagram of the atmospheric simulator, as configured for measurements of the microwave absorption of gaseous sulfuric acid under Venus atmospheric conditions.

Fig. 2 (below): Measured absorptivity (normalized by mixing ratio) of gaseous H$_2$SO$_4$ in a CO$_2$ atmosphere as a function of pressure and frequency.
Figure 3: Map of 2 cm Venus emission (residual relative to emission from uniformly opaque sphere.)

Figure 4: Map of 1.3 cm Venus emission (residual relative to emission from uniformly opaque sphere.)
Orbiter Infrared Radiometer (OIR) experiment (Taylor, et al., 1980). These emission maps will be interpreted using our radiative transfer models, which will incorporate the new formalisms for the opacity from SO₂ and gaseous H₂SO₄.

C. OTHER ACCOMPLISHMENTS

In October 1995, three (3) conference presentations were made at the 1995 AAS/DPS meeting (Kolodner and Steffes, 1995; Suleiman and Steffes, 1995; and DeBoer and Steffes, 1995). The abstracts for these presentations are attached as Appendix B. Two refereed journal papers were also published: Suleiman et al. (1996, reprints previously mailed) and DeBoer and Steffes (1996a, reprints will be mailed when received from publisher). A third refereed paper (DeBoer and Steffes, 1996b) has recently been accepted for publication in Icarus. (Preprints were previously mailed).

Additionally, the 1996 IEEE Judith A. Resnik Award was presented to the Principal Investigator of this grant with the citation, “for contributions to an understanding of the Venus atmosphere through innovative microwave measurements,” acknowledging work accomplished under this grant.

III PLANNED WORK FOR THE UPCOMING GRANT YEAR
(November 1, 1996 - October 31, 1997)

Once the high-accuracy laboratory measurements of the absorptivity and refractivity of gaseous H₂SO₄ are completed, an analytical formalism will be developed, using the existing Poynter/Pickett/Cohen line catalog (1994), which will allow accurate computation of the opacity of the H₂SO₄ under Venus conditions. The formalism to be developed fits the laboratory data to the combined effects of all 55,563 lines by selecting the proper lineshape formalism (Van Vleck-Weisskopf, Ben Reuven, Gross, etc.), in a similar fashion to that used previously to develop formalisms for SO₂ (Suleiman, et al., 1996).

The new formalism will be directly applied to the 13 cm Magellan absorptivity profiles (after subtracting the known absorption from CO₂) to develop high accuracy H₂SO₄ abundance profiles for the Venus atmosphere. Additionally, by using the new profiles and our formalism, we can subtract the effects of the absorption of H₂SO₄ (and CO₂) from the 3.6 cm absorptivity profiles and be left with only absorption due to SO₂, which will then be used to derive SO₂ abundance profiles, using the new formalism we have developed for SO₂ opacity (Suleiman et al., 1996). Details of the new H₂SO₄ formalism will, of course, be published and also provided to investigators working with Venus absorptivity data (e.g. Jenkins at SETI Institute/NASA Ames) so as to be used in developing their new results.

Of equal interest will be the application of this formalism to our microwave radiative transfer model for Venus. A new model for the microwave emission from Venus has been developed by Graduate Student, Mark Kolodner, which is innovative in its full analysis of the effects of atmospheric refraction on limb emission and in its use of Magellan results for modelling the centimeter wavelength surface emission. The first application of this model was described in Suleiman et al. (1996) where the model used the new formalism for SO₂ absorption to place limits on the abundance of SO₂ in the Venus atmosphere, based on disk-averaged observations of the centimeter-wavelength emission.
One key result of the new modeling effort is the determination that the 20-25 GHz range is the most sensitive portion of the Venus microwave emission spectrum to subcloud SO₂. This is significant in that it includes the 1.3 cm wavelength observed with the VLA. Thus, new maps of the 1.3 cm Venus emission can be used to detect spatial variations in the abundance and distribution of SO₂. Similarly, based on our new model for the opacity from gaseous H₂SO₄, it appears as if the 2 cm wavelength emission is especially sensitive to sub-cloud abundance of gaseous H₂SO₄. Thus, the new 2 cm emission maps will be interpreted using our radiative transfer model incorporating the new formalisms for the opacity from SO₂ and gaseous H₂SO₄.

Finally, after the laboratory measurements of gaseous H₂SO₄ are complete, the measurement system will be re-constructed in preparation for measurements of the microwave properties of phosphine (PH₃) under simulated Neptune conditions.

Results from both the laboratory studies and observational work will be presented at the 28th Annual Meeting of the Division for Planetary Sciences of the American Astronomical Society in Tucson, AZ (October 23-26, 1996). These results will also be submitted for publication in Icarus.
IV. PROPOSED BUDGET

PRINCIPAL INVESTIGATOR: Paul G. Steffes (Georgia Institute of Technology)

TITLE: Laboratory Evaluation and Application of Microwave Absorption Properties Under Simulated Conditions for Planetary Atmospheres

GRANT NUMBER: NAGW-533
For the period of November 1, 1996 through October 31, 1997 (Second year of 3-year program)

ESTIMATED COST BREAKDOWN

I. DIRECT SALARIES AND WAGES*: $41,260
   A. Principal Investigator
      Paul G. Steffes
      22% time, calendar year (.20 person-years) $22,329
   B. 1 Graduate Student (S. H. Suleiman)
      50% time, calendar year (.5 person-years) $15,900
   C. 1 Senior Administrative Secretary
      12% time, calendar year (.12 person-years) $3,031

II. FRINGE BENEFITS**: $6,289
   24.8% of Direct Salaries & Wages (less students)

III. MATERIALS, SUPPLIES, AND SERVICES $1,500
   A. Gases, liquids, and supplies (microwave connectors and o-rings) for Experiments $900
   B. Miscellaneous Project Supplies (data storage media) and page charges $600

IV. TRAVEL $1,300
   A. Travel for Student to AAS/DPS Meeting
      (Boston, MA, 5 days duration, airfare $600 plus registration and $100/day) $1,300

   SUBTOTAL - ESTIMATE OF DIRECT COSTS: $50,349

V. OVERHEAD (Indirect Expense)**: $21,651
   43% of Modified Total Direct Cost Base

TOTAL FIRST YEAR BUDGET REQUESTED FROM NASA: $72,000

SUMMARY OF STAFFING REQUEST: SEE SECTION I (ABOVE)

* The salary and wage rates are based on FY97 salaries for the Georgia Institute of Technology. The Georgia Tech Fiscal Year is July 1 through June 30.
** Rates are for the period July 1, 1996 through June 30, 1997 and are subject to adjustment upon DCAA audit and ONR negotiations.

(12) Abstract (Do not write outside this space. Please type.)

   A VLA observation of Venus is proposed to obtain high resolution continuum maps at frequencies of 15 GHz and 22 GHz. These emission maps will be used to detect potential spatial (longitudinal and latitudinal) variations in the abundances of gaseous sulfur dioxide (SO$_2$) and gaseous sulfuric acid (H$_2$SO$_4$) across the disk of the planet. The suggested observation time is in early April 1996 while the VLA is in the C-configuration. The time requested for this observation is 12 hours which can be divided on two consecutive days (6 hours per day).

Please include the full addresses (postal and e-mail) for first-time users or for those that have moved (if not contact author). When your proposal is scheduled, the contents of the cover sheets become public information (Any supporting pages are for refereeing only).
We propose to observe Venus using the Very Large Array (VLA) at 15 GHz and 22 GHz simultaneously. The objective of this observation is to obtain high resolution continuum maps of Venus. These emission maps will be used to detect potential spatial (longitudinal and latitudinal) variations in the abundances of gaseous sulfur dioxide (SO$_2$) and gaseous sulfuric acid (H$_2$SO$_4$) across the disk of the planet. Statistically significant large-scale variations in the 13 cm absorptivity profiles of the sub-cloud Venus atmosphere were observed from the Pioneer-Venus radio occultation data (Jenkins et al., 1991). In addition, small-scale variations in the 3.6 cm and 13 cm opacity profiles were detected from the 1991 Magellan radio occultation measurements (Jenkins et al., 1994). Finally, small and large-scale variations in the emission from the lower atmosphere of the planet were observed in the near infrared images of the nightside of Venus during the Galileo encounter (Carlson et al., and Crisp et al., 1991). These features are likely caused by variations in the sulfur-bearing gases in the lower Venus atmosphere where strong dynamical forces are present.

The frequencies of observation were selected based on their sensitivity to these constituents, as determined using our radiative transfer model. This model incorporates a newly developed Ben-Reuven formalism which provides a more accurate characterisation of the microwave absorption of gaseous SO$_2$ (Suleiman et al., 1995). The model also uses the most current spectral line catalog [Poynter et al., 1994] to compute the microwave absorption of gaseous H$_2$SO$_4$. A 150 ppm mixing ratio of gaseous SO$_2$ below the main cloud layer (based on uniform mixing) is used which is in agreement with recent infrared Earth-based observations [see Besard et al., 1993]. This SO$_2$ mixing ratio also compares well with previous spacecraft in situ measurements [see Oyama et al., 1980 and Gelman et al., 1979]. A 20 ppm mixing ratio of gaseous H$_2$SO$_4$ between 38 and 48 km is used which is consistent with the results from the 1991 Magellan radio occultation experiments [see Jenkins et al., 1994]. Figure 1 shows the range of projected differences in the flux density per beam for a viewing angle of 0° (nadir) as a function of frequency between a Venus atmosphere with only carbon dioxide (CO$_2$), nitrogen (N$_2$), and water vapor (H$_2$O) and a Venus atmosphere with CO$_2$, N$_2$, H$_2$O, and SO$_2$. Figure 2 shows the range of projected differences in the flux density per beam for a viewing angle of 0° (nadir) as a function of frequency between a Venus atmosphere with only CO$_2$, N$_2$, H$_2$O, and SO$_2$ and a Venus atmosphere with CO$_2$, N$_2$, H$_2$O, SO$_2$, and H$_2$SO$_4$. Note from Figures 1 and 2 that the largest drop in the flux density at nadir due to the absorption from gaseous SO$_2$ and gaseous H$_2$SO$_4$ occurs in the K-band (20-25 GHz) and U-band (12-16 GHz) portions of the emission spectrum, respectively. Thus, simultaneous observations in these regions would be most sensitive to detecting potential spatial variations in the abundances of gaseous SO$_2$ and gaseous H$_2$SO$_4$ which are correlated in position and time and are both contributing to the integrated opacity at each frequency.

Although an observation of the Venus emission was conducted with the VLA in December 1981 at 15 GHz and 22 GHz [Janssen et al., 1982], images obtained at both frequencies had large rms noise levels (±8 10 Kelvins or more). Thus, measurements of the effects of gaseous SO$_2$ at 22 GHz and gaseous H$_2$SO$_4$ at 15 GHz from these images were difficult since the possible variations in the brightness temperature are only on the order of 5-10 Kelvins at both frequencies. The current system is significantly more sensitive and thus, less noisy images could be obtained.

We suggest conducting the observation in February through mid April 1996, when the VLA will be in the C-configuration. The apparent angular diameter of Venus will be about 15-30 arc sec and its distance from Earth will be about 0.7 arc sec. The time requested for this observation is 12 hours which can be divided on two consecutive days (6 hours per day), if necessary. This requested time includes both the on-source integration time and the calibration time which is chosen such as to optimise coverage in the U-V plane and hence construct a reasonable continuum image.

Figure 1: Range of projected differences in the flux density per beam for a viewing angle of 0° (nadir) as a function of frequency between a Venus atmosphere with only CO$_2$, N$_2$, and H$_2$O and a Venus atmosphere with CO$_2$, N$_2$, H$_2$O, and SO$_2$. The mixing ratio for gaseous SO$_2$ is 150 ppm (uniformly mixed) below 48 km.
Figure 2: Range of projected differences in the flux density per beam for a viewing angle of 0° (nadir) as a function of frequency between a Venus atmosphere with only CO₂, N₂, H₂O, and SO₂ and a Venus atmosphere with CO₂, N₂, H₂O, SO₂, and H₂SO₄. The mixing ratio for gaseous H₂SO₄ is 20 ppm for altitudes between 38 and 48 km.
New laboratory measurements of the microwave opacity of sulfuric acid vapor under simulated Venus conditions

M. A. Kolodner (School of Physics, Georgia Institute of Technology, Atlanta, Georgia, 30332-0430), P. G. Steffes (School of Electrical and Computer Engineering, Georgia Institute of Technology, Atlanta, Georgia, 30332-0250)

New laboratory measurements of the microwave opacity of H$_2$SO$_4$ in a CO$_2$ environment are being performed at 2.25 GHz (13.3 cm), 8.54 GHz (3.5 cm), 16.4 GHz (1.83 cm), and 21.7 GHz (1.38 cm) at a temperature of 590 Kelvins and at pressures ranging from 2 to 6 atmospheres. The experimental setup and approach is similar to that used by Steffes (Icarus 64, p. 576, 1985 & Astrophys. J. 310, p. 482, 1986) but a significant reduction in the uncertainty of the measurements is achieved due to our ability to account for changes in the dielectric properties of the resonators when a lossy gaseous mixture is introduced into them. Based on our absorptivity measurements and the new Poynter-Pickett-Cohen spectral line catalog for H$_2$SO$_4$, a new line shape model is being developed. This model, together with a Ben-Reuven line shape model for the microwave opacity of gaseous SO$_2$ in a CO$_2$ environment developed by Suleiman et al. (submitted to JGR Planets, April 1995), will be incorporated into a radiative transfer model to evaluate the microwave emission spectrum of Venus. Based on radio observations of Venus, new estimates on the disk averaged abundances of gaseous SO$_2$ and H$_2$SO$_4$ vapor in the Venus atmosphere can be inferred. Finally, these microwave opacity models will be used to infer specific abundance profiles of gaseous SO$_2$ and H$_2$SO$_4$ vapor from measured absorptivity profiles of the Venus atmosphere obtained during the 1991 Magellan radio occultation experiments (Jenkins et al., Icarus 110, p. 79, 1994).

Radiative Transfer Models for Venus Microwave and Millimeter-Wave Emission using a Ben-Reuven Formalism for SO₂ Absorption

S. H. Suleiman, P. G. Steffes (School of Electrical and Computer Engineering, Georgia Institute of Technology, Atlanta, Georgia, 30332-0250)

Several abundance profiles for gaseous sulfur dioxide (SO₂) in the Venus atmosphere have been inferred from spacecraft experiments and Earth-based radio astronomical observations (Oyama et al., J. Geophys. Res. 85, 8141-8150, 1980; Hoffman et al., J. Geophys. Res. 85, 7882-7890, 1980; Gelman et al., Space Res. 20, 219, 1979; Bertaux et al., submitted to J. Geophys. Res., 1995; Bezard et al., Geophys. Res. Lett. 20, 15, 1587-1590, 1993; Good and Schloerb, Icarus 53, 538-547, 1983; Steffes et al., Icarus 84, 83-92, 1990). A radiative transfer model has been developed to examine the effects of these SO₂ abundance profiles on the microwave and millimeter-wave emission of Venus. This model incorporates the newly developed Ben-Reuven line shape formalism (Suleiman et al. submitted to J. Geophys. Res., 1995) which provides a more accurate characterization of gaseous SO₂ absorptivity in the Venus atmosphere as compared to other formalisms. The resulting brightness temperature spectra using these abundance profiles are compared with existing observations to examine their consistency. Furthermore, a future observation of Venus using the Very Large Array (VLA) is proposed at 1.3 and 2 cm. This observation along with the measured results from the Magellan radio occultation experiments (Jenkins et al., Icarus 110, 79-94, 1994) will enable us to resolve the spatial and temporal variations of SO₂ abundance in the Venus atmosphere.

Potential Effects of Phosphine (PH₃) on the Microwave and Millimeter Wave Opacity and Emission from the Atmosphere of Neptune

D. R. DeBoer (Hughes STX Corp., Greenbelt, MD 20770), P. G. Steffes (School of Elec. and Comp. Eng., Georgia Inst. of Tech., Atlanta, GA 30332-0250)

In order to best match the most reliable disk-averaged microwave and millimeter-wave emission measurements of Neptune (1 mm to 20 cm) and not exceed the measurements of 13 cm and 3.6 cm absorptivity made by Voyager 2 at Neptune (Lindal, Astron J. 103, 967-982), a Neptune atmosphere where the abundance of H₂S is greater than that of NH₃ below the putative NH₄SH cloud in the deep atmosphere is required (DeBoer and Steffes, B.A.A.S. 26, 1094, 1994). While such an atmosphere (e.g. 78% H₂, 19% He, 3% CH₄, plus 40 x solar H₂S and 0.2 x solar NH₃) gives an excellent fit to the microwave and millimeter-wave emission spectra, its opacity is too low at 13 cm and 3.6 cm to explain the Voyager radio occultation results. It is possible, however, to match both the emission spectra and the Voyager results by adding phosphine (PH₃) to the model.

Phosphine has been detected on Jupiter and Saturn at its strong rotational resonance (267 GHz, see, e.g., Weisstein and Serabyn, Icarus 84, 367-381). The results from Saturn inferred a 10x solar abundance. Preliminary estimates with our Neptune radiative transfer model suggest that a PH₃ abundance between 10x and 20x solar best fits the microwave data. Estimates of the microwave absorption spectrum of PH₃ have been made using the Poynter, Pickett, and Cohen line catalog (available on-line from JPL), and assuming Van Vleck-Weisskopf lineshapes with a range of possible broadening parameters. In the future, we plan to conduct laboratory measurements of the cm and mm wave opacity of PH₃ in an H₂/He atmosphere to more accurately predict this effect.
