The invention is embodied in a method of controlling a robot manipulator moving toward a target frame F₀ with a target velocity v₀ including a linear target velocity v and an angular target velocity \( \omega \), to smoothly and continuously divert the robot manipulator to a subsequent frame F₁ by determining a global transition velocity v₁, the global transition velocity including a linear transition velocity v₁ and an angular transition velocity \( \omega_1 \), defining a blend time interval \( \tau \) within which the global velocity of the robot manipulator is to be changed from a global target velocity v₀ to the global transition velocity v₁ and dividing the blend time interval \( \tau \) into discrete time segments \( \delta \). During each one of the discrete time segments \( \delta \) of the blend interval \( \tau \), a blended global velocity v of the manipulator is computed as a blend of the global target velocity v₀ and the global transition velocity v₁, the blended global velocity v including a blended angular velocity \( \omega \) and a blended linear velocity v, and then, the manipulator is rotated by an incremental rotation corresponding to an integration of the blended angular velocity \( \omega \) over one discrete time segment \( \delta \).

TASK SPACE ANGULAR VELOCITY BLENDING FOR REAL-TIME TRAJECTORY GENERATION

ORIGIN OF THE INVENTION

The invention described herein was made in the performance of work under a NASA contract, and is subject to the provisions of Public Law 96-517 (35 USC 202) in which the contractor has elected not to retain title.

BACKGROUND OF THE INVENTION

1. Technical Field

The invention relates to a compliant motion control system for controlling a robot using angular velocity blending in task space in performing specific tasks.

2. Background Art

The specification below makes reference to the following publications by number:

References

1 Introduction

Just as manipulator control can be effectively accomplished in joint space or task space, trajectories for the manipulator can also be specified in joint or task space. Typically, the trajectory is specified in the same space in which the controller is working. However, conversion techniques can be used to translate the specified trajectory to the control space. For instance, inverse kinematics applied to a task space trajectory will provide setpoints to a joint space controller. Since task space trajectory specification is usually considered most useful (especially with task space control), the converse translation of a joint space trajectory to task space is uncommon.

Joint space trajectory generation is straightforward since each joint may be treated independently [8, 1, 3]. Typically, motion between specified joint values is dictated with a third, fourth, or fifth order polynomial. Some extension and optimization of this technique have been proposed [5, 14].

Task space trajectory generation has been addressed more extensively, because of the complexity inherent in it. Whitney proposed Resolved Rate control [15] to easily enable straight line motion or constant axis rotation of an end effector. However, this technique does not inherently address extended trajectory generation considerations. Foremost among these is the problem of blending changes in end effector orientation. Paul [8, 10] proposed blending of the Euler angles describing the relations of the initial and final frames to the intermediate one. This method blends one orientation to the next, but the path generated is not intuitively obvious. Worse, he proposes changing one Euler angle with a different blend profile from the others. Alternatively, Canny [2] utilizes quaternions to describe orientation. However, since he was addressing a different problem (collision detection), he does not discuss the issues of blending the quaternions. Craig [3] utilizes the similar angle-axis formulation, but represents the orientation of each via frame with respect to the world frame, not the previous frame as Paul had done. Thus, the blend of orientation parameters will produce a motion path that is dependent on the relation of the via frames to the world frame, not just their relation to each other. Finally, Lloyd and Hayward [6] developed an elegant method for creating variable position blend paths, but do not show an extension of the method for orientations.

As will be seen, Taylor [13] has proposed a scheme that provides smooth, intuitive, and repeatable position and orientation blends. Its major drawback is computational complexity. This paper presents a velocity based method that achieves the same results with a simpler formulation and significantly reduced computation time.

The next section presents the terminology employed for the solution description. Section 3 presents the proposed velocity blending formulation and described possible blend profile functions. Section 4 quickly discusses position path blending. Orientation blending is extensively discussed in Section 5, where Taylor's method is reviewed, angular velocity blending is presented, and the second order difference between them is analyzed. Sections 6 and 7 discuss implementational considerations and computational costs associated with the algorithms and show why velocity blending is preferable. Finally, Section 8 describes the results of simulation and real-time implementation.

2 Velocity Blending Terminology

A task frame is defined as the set containing the rotation matrix that specifies the end effector orientation, \( R \), the end
Typically the end effector orientation is specified by a rotation matrix composed of the vectors defining the end effector orientation with respect to the stationary world frame [8].

\[
\mathbf{R} = [\mathbf{n}, \mathbf{o}, \mathbf{p}]
\]  

(2)

To specify a frame, rotation matrix, or vector with respect to another frame, the former is proceeded with a superscript. For instance, a frame, rotation, or vector with respect to the world frame is denoted by \( \mathbf{R}_{\text{w}} \), \( \mathbf{R}_{\text{w}} \), or \( \mathbf{v}_{\text{w}} \), respectively.

In between two sequential frames, the desired linear velocity of the end effector is simply the difference in velocities of the successive frames:

\[
\mathbf{v}_k = \mathbf{v}_k - \mathbf{v}_{k-1}
\]  

(3)

The angular velocity is obtained from the equivalent angle-axis formulation for a rotation from one frame to another [3]:

\[
\omega_k = k \cdot \frac{\mathbf{o}_k}{T_k}
\]  

(4)

\[
k \sin \phi_k = \frac{1}{2} \left( \mathbf{n}_{k-1} \times \mathbf{n}_k + \mathbf{o}_{k-1} \times \mathbf{o}_k + \mathbf{p}_{k-1} \times \mathbf{p}_k \right)
\]  

(5)

\[
\cos \phi_k = \frac{1}{2} \left( \mathbf{n}_{k-1} \cdot \mathbf{n}_k + \mathbf{o}_{k-1} \cdot \mathbf{o}_k + \mathbf{p}_{k-1} \cdot \mathbf{p}_k - 1 \right)
\]  

(6)

where motion at velocity \( \omega_k \) for time \( \Delta t \) causes a rotation of:

\[
\mathbf{R}(\omega_k \Delta t) = \mathbf{R}(k, \phi)
\]  

(7)

with \( \mathbf{R}(k, \phi) = \left[ k \mathbf{n}_k \mathbf{V}_k + \mathbf{C}_k \mathbf{V}_k \mathbf{V}_k - k \mathbf{S}_k \mathbf{S}_k \mathbf{S}_k \mathbf{V}_k + k \mathbf{S}_k \mathbf{V}_k \right] \),

\[
k \mathbf{n}_k \mathbf{V}_k + \mathbf{C}_k \mathbf{V}_k \mathbf{V}_k - k \mathbf{S}_k \mathbf{S}_k \mathbf{V}_k + k \mathbf{S}_k
\]  

40

The invention is embodied in a method of controlling a robot manipulator moving toward a target frame \( \mathbf{F}_0 \) with a target velocity \( \mathbf{v}_0 \) including a linear target velocity \( \mathbf{v} \) and an angular target velocity \( \mathbf{\omega}_0 \), smoothly to divert the robot manipulator to a subsequent frame \( \mathbf{F}_1 \), the target frame being associated with a target transition time \( T_0 \) and the subsequent frame being associated with a subsequent transition time \( T_1 \), by determining a global transition velocity \( \mathbf{v}_1 \) necessary to move the manipulator from the target frame \( \mathbf{F}_0 \) to the subsequent frame \( \mathbf{F}_1 \) within the subsequent transition time \( T_1 \), the global transition velocity including a linear transition velocity \( \mathbf{v}_1 \) and an angular transition velocity \( \mathbf{\omega}_1 \), defining a blend time interval \( T_0 \) within which the global velocity of the robot manipulator is to be changed from the global target velocity \( \mathbf{v}_0 \) to the global transition velocity \( \mathbf{v}_1 \) and dividing the blend time interval \( T_0 \) into discrete time segments \( \Delta t \). During each one of the discrete time segments \( \Delta t \) of the blend interval \( T_0 \), the following is performed: (a) compute a blended global velocity \( \mathbf{v} \) of the manipulator as a blend of the global target velocity \( \mathbf{v}_0 \) and global subsequent velocity \( \mathbf{v}_1 \), the blended global velocity \( \mathbf{v} \) being at least approximately equal to the target global velocity \( \mathbf{v}_0 \) at the beginning of the blend time interval and at least approximately equal to the global transition velocity \( \mathbf{v}_1 \) at the end of the blend time interval, the blended global velocity including a blended angular velocity \( \mathbf{\omega} \) and a blended linear velocity \( \mathbf{v} \), and then, (b) rotate the manipulator by an incremental rotation corresponding to an integration of the blended angular velocity \( \mathbf{\omega} \) over one discrete time segment \( \Delta t \).

BRIEF DESCRIPTION OF THE DRAWINGS

FIGS. 1A and 1B are graphs showing the blend speed for a spectrum of angles (0, 45, 90, 135 and 180 degrees) between the initial and final velocities, for the case in which the magnitudes of the initial and final velocities are equal using linear velocity blending (FIG. 1A) and third order polynomial velocity blending (FIG. 1B).

FIGS. 2A and 2B are graphs comparing linear, third order polynomial and cycloidal velocity blends of two orthogonal velocities of equal magnitude (FIG. 2A) and two parallel velocities of unequal magnitude (FIG. 2B).

FIGS. 3A and 3B are graphs showing the spatial paths (FIG. 3A) and temporal paths (FIG. 3B) for a transition between two orthogonal velocities of equal magnitudes for a maximum acceleration magnitude of 10m/s².

FIG. 4 is a graphical depiction of the velocity blending process of Equation 36.

FIGS. 5A and 5B are diagrams depicting the spatial transition of the target frame (FIG. 5A) and the angular velocity vector (FIG. 5B) during an orientation blend using the process of Equation 36 with linear blending.

FIGS. 6A, 6B and 6C are graphs illustrating the component values of the unit vectors of the frames shown in FIG. 5A for the n, o and \( \alpha \) components, respectively.

FIG. 7 is a graph depicting the incremental blending of the process of Equation 47.

FIG. 8 is a graph depicting the blending of the process of Equation 57 in accordance with the present invention.
FIGS. 9A and 9B are diagrams depicting the spatial transition of the target frame (FIG. 9A) and the angular velocity vector (FIG. 9B) during an orientation blend using the process of Equation 57 with linear blending.

FIGS. 10A, 10B and 10C are graphs illustrating the component values of the unit vectors of the frames shown in FIG. 9A for the n, o and a components, respectively.

FIG. 11 is a simplified schematic block diagram of a robot control system employed in carrying out the invention.

FIG. 12 is a block flow diagram illustrating the blending process of the present invention in accordance with a preferred embodiment.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

3 Angular Velocity Blending

To move smoothly from one segment to another, the velocities of the segments must be blended together. To achieve this, many strategies employing linear velocity v have been suggested [9, 13, 5, 14, 6, 7]. These techniques are discussed below within the framework of the present invention.

The present invention introduces the concept of blending angular velocity by blending a global velocity vector v that includes both an angular velocity vector w and the linear velocity vector v. The following discussion utilizes the global velocity v of Equation 11 which includes angular velocity w with the following convention:

\[ \begin{align*}
v_a &= v_t \\
v_b &= v_{tf} \\
\tau &= t - (t_2 - t)
\end{align*} \]

There are several simple choices available for blend functions. These are provided below, along with the resultant form of the velocity, acceleration, and blend time.

Linear Velocity Blending [13]

\[ f(s) = s \]

\[ a = \frac{v_b - v_a}{2t} \]

\[ 2t = \frac{v_b - v_a}{|v_b - v_a|} \]

Third Order Polynomial Velocity Blending [9, 5]

\[ f(s) = -2s^3 + 3s^2 \]

\[ a = \frac{(v_b - v_a)}{2t} \]

\[ 2t = \frac{v_b - v_a}{|v_b - v_a|} \]

Cycloidal Velocity Blending [7]

\[ f(s) = \sin^2 \frac{\pi}{2} s \]

\[ a = \frac{(v_b - v_a)}{2t} \]

\[ 2t = \frac{v_b - v_a}{|v_b - v_a|} \]

The cycloid has a functional form very close to that of the O(3) polynomial, but does not have a discontinuous jerk (the derivative of the acceleration). In turn, the O(3) polynomial is superior to the linear form since the latter has discontinuous acceleration (and infinite jerk). The strength of the linear
where \( p_i \) is the initial position as the blend is entered. The form of the integral of the blend function determines the spatial form trace by the path. For the three blend functions considered, we have:

- Linear: \( f(s) = \frac{1}{2} s^2 \)  
- \( O(3) \) Polynomial: \( f(s) = -\frac{1}{2} s^4 + s^2 \)  
- Cycloidal: \( f(s) = \frac{s}{2} - \frac{1}{2\pi} \sin(\pi s) \)

Equation (33) provides a second order polynomial, and the blend is parabolic. Equation (34) provides a fourth order polynomial, and the blend that is steeper. (Higher order even polynomial functions will be increasingly steeper.) The cycloidal blend path remains sinusoidal, but has the addition of a linear term.

The graphs of FIG. 3 show the spatial and temporal paths for a transition between \( v_1 \) and \( v_2 \), such that \( v_1, v_2, v_1, v_2 \) with \( \|v_1\| = 10 \text{ m/s}^2 \). It is apparent from FIG. 3A that tighter cornering can be accomplished with polynomial and cycloidal blending. However, this requires longer blend times (or larger acceleration, and therefore greater joint torques from the actuators). FIG. 3B shows the positions as a function of time, which are essentially the integrals of the velocities shown in FIG. 3A. The form of these curves also represents the functional form of the position blend functions, Equations (33)-(35).

5.1 Rotation Matrix Blending for Orientation

In reference [13], Taylor proposed a method of blending orientation based on rotation matrices. A generalization of this method will be presented here. In this method, the amount of rotation contributed by each rotation matrix is scaled with the previously presented blend functions:

\[ R(s) = R_a \circ R_b \circ [a_2(t-s-f(s))] \circ R_a \circ [a_2(t-f(s))]. \]  

The graph of FIG. 4 provides a graphical depiction of this blending method. Prior to the blend there is motion away from the orientation of the previous frame, \( F_{i-1} \), and toward the intermediate orientation, \( a \). The constant angular velocity before the blend is \( \omega_a \), and the blend begins at orientation \( o \). In this method, for each interval after \( a \) a rotation is constructed and applied according to the rotation matrix blending described by Equation (36) or (37). After the normalized blend time \( s \) has become unity, the commanded angular velocity will be \( \omega_a \), and the commanded orientation is \( b \). After this time, the trajectory continues toward the next target frame, \( F_{i+1} \), at the constant angular velocity of \( \omega_a \). To avoid faceted motion through the blend, the normalized time must be incremented in infinitesimal intervals.

In reference [13], the formulation of this blending scheme is presented with respect to frame a, not o. This alternate representation can be seen by starting with Equation (36), and utilizing the identity.

Further, reference [13] only considers the linear blend case with \( f(s) = s^2 \). This gives:

\[ R(t) = R_a \circ R_b \circ [a_2(t-s-f(s))] \circ R_a \circ [a_2(t-f(s)]. \]  

Substituting Equations (4), (14), and (15) yields:

This is the form of the rotation blend presented in [13]. The diagrams of FIG. 5 provide a graphical depiction of change in the target frame (FIG. 5A) and the direction of the angular velocity vector (FIG. 5B). (A constant spatial velocity has also been used, to spread out the vectors for pictorial clarity.) The graphs of FIG. 6 show the change in the target frame basis vector components under this transformation.

5.2 Incremental Rotation Blend Components

It is informative to look at the rotations that represent the individual incremental rotation between successive time increments when utilizing Equation (36). Consider the difference between successive frames depicted in FIG. 7.

The incremental rotation between successive orientations is:

\[ R_p = R \circ \omega_p \circ R_b \]

\[ R_p = R \circ \omega_p \circ R_b \]

\[ R_p = R \circ \omega_p \circ R_b \]

\[ R_p = R \circ \omega_p \circ R_b \]

The graph of FIG. 4 provides a graphical depiction of this blending method. Prior to the blend there is motion away from the orientation of the previous frame, \( F_{i-1} \), and toward the intermediate orientation, \( a \). The constant angular velocity before the blend is \( \omega_a \), and the blend begins at orientation \( o \). In this method, for each interval after \( a \) a rotation is constructed and applied according to the rotation matrix blending described by Equation (36) or (37). After the normalized blend time \( s \) has become unity, the commanded angular velocity will be \( \omega_a \), and the commanded orientation is \( b \). After this time, the trajectory continues toward the next target frame, \( F_{i+1} \), at the constant angular velocity of \( \omega_a \). To avoid faceted motion through the blend, the normalized time must be incremented in infinitesimal intervals.

In reference [13], the formulation of this blending scheme is presented with respect to frame a, not o. This alternate representation can be seen by starting with Equation (36), and utilizing the identity.
where $e$ is the infinitesimal rotation operator [4]. This result indicates each incremental rotation of Taylor's scheme is equal, to first order, to the rotation provided by the instantaneous angular velocity. This implies that it is possible to blend the angular velocities utilizing Equation (17), and obtain the incremental rotations from the value of the instantaneous angular velocity.

5.3 Angular Velocity Blending for Orientation

As was discussed in the last section, the incremental rotations of an orientation blend can be approximated by utilizing the instantaneous angular velocity provided by Equation (17). Thus, the orientation of the target frame can be computed by utilizing Equations (1), (4), (7), (11), and (17):

$$s_n = n/N; \Delta s = 1/N$$

where $N$ is the total number of steps for the complete blend. FIG. 8 provides a graphical depiction of this blending method. Before the blend, there is motion away from the orientation of the previous frame, $F_{n-1}$, and toward the intermediate orientation, $\alpha = F_0$. The constant angular velocity before the blend is $\omega_0$. The blend begins at orientation $\alpha$.

For each interval after $\alpha$, a rotation is constructed and applied according to the angular velocity blending provided by Equation (17). After the normalized blend time $s$ has become unity, the commanded angular velocity will be $\omega_0$. Ideally, the blend will be complete at the desired orientation, $\alpha$, where the trajectory continues toward the next target frame, $F_{n+1}$.

In practice, velocity-based blending can provide equivalent blends to the rotation matrix method described previously. The graphs of FIG. 9 depict the change in the target frame (FIG. 9A) and the direction of the angular velocity vector (FIG. 9B) for third order polynomial angular velocity blending, with $l_{\text{max}} = 10$ m/s². A constant linear velocity is also utilized to spread out the origins of the frames for clarity. The graphs of FIG. 10 show the change in the target frame basis vector components under this transformation. Comparing FIGS. 9 and 10 with FIGS. 5 and 6, it is seen that there is little difference between blending schemes, even when using different blending profiles.

5.4 Compensation for Second Order Error from Angular Velocity Blending

Looking closely at FIG. 10, it can be seen that there is some small residual error in the components of the basis vectors. This error results from the second order error introduced by the infinitesimal rotation approximation in Section 5.2. This can be understood by considering how the angular velocity blending effects the rotation blending. Consider first the case of total completion of rotation by $\omega_0$ before rotation by $\omega_0$ begins. In this case, the resulting rotation is exact:

$$R_{\text{cor}} = R_0(\Delta t)^2/2 R_0(0)$$

$$R_{n} = R_{n-1} \Gamma_{n-1} \ldots \Gamma_{1} a \Gamma_{0} a \Gamma_{N-1} \ldots \Gamma_{1} a \Gamma_{0} a$$

where the rotations $a R_0$ and $a R_{i}$ have been divided into $N$ parts. Blending the angular velocities is equivalent to changing the order of some of the rotations at the center of this chain. For instance, utilizing the infinitesimal rotation approximation [4]:

$$R_{\text{cor}} = R_{\text{cor}}^{(1+e)}(1+e^2) R_{\text{cor}}^{(1+e)} R_{\text{cor}}^{(1+e)} R_{\text{cor}}^{(1+e)}$$

The lack of these second order terms explains the small error introduced by angular velocity based orientation blending.

The change in position of $a R_0$ and $a R_{i}$ operators in the sequence is reminiscent of diffusion. As the $a R_0$ 'diffuse' farther to the right, and the $a R_{i}$ 'diffuse' farther to the left, the changed in orientation becomes more blended. Since the infinitesimal rotations can be represented by their angular velocity equivalents, the diffusion profile is equivalent to the velocity blend profile. For instance, the shape of the cycloidal blend profile in FIG. 2B indicates more diffusion than the linear one. Further smaller values of $l_{\text{max}}$ also imply more diffusion, since they spread out these curves. More diffusion introduces second order error. Therefore, linear blends and high acceleration blends result in less residual error for a given value of $l_{\text{max}}$. However, linear blends will result in more error if the blend time is fixed instead of the acceleration. This can be understood by lessening the slope of the linear blend line in FIG. 2B, thus introducing more diffusion.

To provide some quantitative description to this discussion, the following table shows the magnitude of the orientation error for the example previously considered.

<table>
<thead>
<tr>
<th>Blend Type</th>
<th>$l_{\text{max}} = 10$ m/s²</th>
<th>$l_{\text{max}} = 5$ m/s²</th>
</tr>
</thead>
<tbody>
<tr>
<td>Linear</td>
<td>0.29°</td>
<td>1.16°</td>
</tr>
<tr>
<td>O(3) polynomial</td>
<td>0.39°</td>
<td>1.56°</td>
</tr>
<tr>
<td>Cycloidal</td>
<td>0.41°</td>
<td>1.62°</td>
</tr>
</tbody>
</table>

It is apparent that these errors are small and may be corrected (as described below). Substantially larger errors are not possible since they would require much smaller accelerations which require longer blend times. Too large of a blend time multiplied by $\omega_0$ or $\omega_0$ would indicate a rotation greater than 180° in the initial or final legs. Such large rotations have been precluded by Equation (5).

While this small error introduced by one blend does not necessarily require compensation, the summation of this error over successive blends may become significant. To compensate for the residual error, we propose the use of a correction term which is calculated at the end of every velocity based blend of orientation. This term is the incremental rotation from the resultant frame to the desired frame at the end of the orientation blend:

$$R(\Delta t) = R_0(\Delta t)^2/2 R_0(0)$$

In practice, $k_{\text{cor}}$ and $c_{\text{cor}}$ can easily be calculated by Equations (5) and (6). A correction velocity may then be
calculated and applied to the leg of the trajectory being entered, for the time specified to the next via frame:

\[ \theta_{cor} = \theta_{cor} \cdot c(c/T_{i} + 1) \]  

This correction term is modified by a gain, \( K_{cor} \), and added to the angular velocity \( \dot{\omega}_0 \). (Since it is very small in magnitude, concerns about changing the value of \( \dot{\omega}_0 \) have been ignored.) The gain is needed to maintain stability in what is effectively a low bandwidth feedback controller. If Equations (57) and (63) were linear, this discrete time controller would be trajectory stable for \( 0 \leq K_{cor} \leq 1 \). However, for the nonlinear orientation blending, we have empirically found stability for gains of \( 0 \leq K_{cor} \leq 0.3 \).

### 6 Implementation Considerations

Three main implementational considerations have been accommodated in our scheme: maximum acceleration, minimum blend time, and velocity summation.

#### 6.1 Maximum Acceleration

Since the calculated trajectories are to be executed by real manipulators, the commanded acceleration must be limited to what is achievable. Further, the achievable task space acceleration of the arm depends on the configuration of the robot arm. In different parts of the workspace, different task space accelerations are possible. Therefore, two possibilities exist: 1.) limit all task space accelerations to the worst case acceleration of the arm, or 2.) create a complete map of the achievable task space accelerations, and limit the trajectory blending accordingly. However, creating and accessing such a map is anticipated to be very cumbersome. Therefore, we have currently chosen to work with the first, and simpler, of these two options.

Another consequence of limited acceleration is that it erodes the straight line leg segments of the trajectory between via frames. For a small enough acceleration, one blend will end as another begins. For accelerations smaller than this, one blend would have to begin before another ends. We do not permit this to occur. In this case, the acceleration is increased level of acceleration is not achievable by the arm, then the via frames are not reasonably selected and unavoidable position errors will occur.

#### 6.2 Minimum Blend Time

Due to the discrete nature of the computer implementation of these algorithms, it is necessary to specify a minimum number of iterations over which an acceleration is specified. From Equation (52) this quantity is the minimum allowed value of 2\( \pi \). If a minimum is not specified, the calculated blend time may become comparable to the algorithm cycle time. Thus, the calculated velocity and position will be discontinuous, providing poor input to the arm controller.

We have empirically determined and utilized a minimum value of twenty iterations per blend. A direct consequence of this specification of 2\( \pi \) is that the minimum allowed acceleration is also limited. If more acceleration is desired, and the manipulator is capable of it, then 2\( \pi \) should be reduced. However, to keep the same number of iterations per blend with a reduced 2\( \pi \), the algorithm rate must be increased proportionally.

#### 6.3 Velocity Summation

To be able to modify commanded trajectories with other control inputs, the commanded variable must be a velocity (a generalized flow variable), not a position [11]. Fig. 11 shows a system for implementing one embodiment of the invention. Although not shown in the drawing, the trajectory generator optionally may be subject to modification by the input of a joystick or a proximity sensor monitor process. In FIG. 11, a trajectory generator 10 performs the velocity blending process described above to produce a desired sequence of desired end effector frames or positions. These are output to a manipulator control system Cartesian control controller 20. The controller 20 computes and outputs a command angle \( \theta _0 \) to a robot arm controller 30 (in this case, the arm controller for the Robotics Research K-1207 Arm). The arm controller 30 converts the command angle to motor currents and outputs the motor currents to servos in a robot arm 40 (in this case, a Robotics Research K-1207 Arm). The robot arm 40 returns servo encoder counts to the arm controller 30, which computes therefrom and outputs corresponding angle measurements \( \theta_m \) to a forward kinematics processor 50. The forward kinematics processor 50 computes and outputs a corresponding measured frame \( F_m = x_m \) to the trajectory generator 10 and computes and outputs a Jacobian transformation matrix \( J \) to the manipulator controller 20. The Cartesian controller 20 and the forward kinematics processor 50 perform the foregoing operations and computations using conventional techniques well known in the art. The arm controller 30 and the robotics arm 40 are commercially available devices.

Utilizing the velocity blending scheme described in this specification with reference to Equation 57, velocity output is obtained directly. Alternatively, if analytic integration of position is used (as in Equation (32)), or if rotation matrix orientation blending is used (as in Equation (36)), then the velocity must be obtained by differencing the reference frames. As will be seen in the next section, this requires extra computation not needed with a purely velocity based scheme.

#### 7 Computational Costs

Table I provides an outline of the computational steps and costs for both position-based and velocity-based blending. The equations involved in each step are also summarized. Finally, an estimate of the computational complexity is given by stating the number of additions, subtractions, multiplies, and divides required, as well as the trigonometric (and square root) operations needed. Under the operations column, the values are the number of standard math operations (+,−, ×, ÷) and the number of trigonometric and other math operations (e.g., sin, cos, sqrt, and so forth). The top section of the table reviews some common steps needed for both schemes. Of these, the frame differencing and frame incrementing are very costly. The calculation of \( f(s) \) or \( f'(s) \) is variable since it depends on the blend functions chosen.

The second and third sections of the table show the algorithmic differences between the position/orientation blending and the velocity blending methods. The most striking difference between the two formulations is the reduced computational cost of the velocity blending method. During a blend it requires only 12 operations, while the position/orientation method requires 263 operations plus eight costly trig or square root calls. The situation is much the same during the straight line leg segments of the trajectory, where the velocity based scheme requires zero operations, while a completely position based scheme requires 160 plus 5. The efficiency of the velocity based scheme is paid for by the overhead necessary during the transition from blend to leg segments. At this juncture, the velocity scheme must make 207 plus 6 operations, while the position/orientation scheme requires only 69 plus 2. However, this overhead occurs only once for each via frame, compared to the hundred or thousands of iterations that occur for the blend or leg segment.
computations. Obviously, velocity blending introduces a significant computational savings. It is important to note that some of the computational advantage of velocity blending is introduced by the assumption that the output of a trajectory generator must be a velocity. The position/orientation scheme must utilize a velocity calculation step during the blend and leg segments which costs 69 plus 2 operations. However, even without this step the velocity blending method is significantly faster. Further, it was shown in the last section why velocity output is more useful.

One other computational burden is introduced to the position/orientation method by the assumption that position, [p,k,ao,aw], is specified as a function of time during the leg segment. Alternatively, the leg segment velocity could be precomputed and utilized directly as in the velocity blend method. Since k is constant during the leg segment, no errors would be introduced. Also, the leg velocity must be computed anyway if the maximum acceleration checks are to be performed (as is assumed).

8 Implementation

We have implemented this algorithm on an SGI Iris workstation for simulation, and on a VME based 68020 microprocessor for control of 7 DOF Robotics Research K-1207 Arm. The end-effector of the robot arm carries an array of sensors: two CCD cameras, two proximity sensors, an optical pyrometer, a gas sensor, and a force sensor. The addition of eddy-current and contact acoustic sensors are planned. While our frame to frame motions are designed to aid inspection by these devices, the presented technique is obviously extensible to motion required for purposes other than inspection.

8.1 Experimentation

The blending algorithm has also been implemented for real-time control on a 12.5 MHz Heurikon 68020 processor. For the tests, a trajectory similar to the simulation trajectory has been executed. However, since the robot base position is fixed, the size of the inspection area is restricted. A total of twelve via frames are used to scan a rectangular shape about half as large as that in the simulation. Linear blending was arbitrarily chosen for these tests. During experiments the minimum time between frames is 3 seconds. The real-time process runs at 44 Hz, or ~22.7 ms, giving approximately 132 iterations for each frame to frame motion. (The control rate is governed by other control software, not the processing requirements of the trajectory blending algorithm, which we have shown to be quite minimal.) The position gain was Kp=20, and the trajectory correction gain was Kcor=0.3. The minimum blend time was tmin ~20 iterations, or about a half second. The maximum acceleration was lalma=10 m/s².

9 Angular Velocity Blending Processing Description

The angular velocity blending method described above is now described in greater detail with reference to the steps depicted in FIG. 12.

The process begins by initializing key parameters (block 100 of FIG. 12), by setting the index n to one, setting the current global velocity v to the initial velocity v0 to zero, while setting the current frame F to the measured frame of reference Fmear and setting the current time t to the minimum blend time tmin. The previous frame corresponds to F, of the graph of FIG. 8.

Typically, the user specifies the next target frame F0 corresponding to F, or point a of FIG. 8, the subsequent frame F1 corresponding to Fm+1 of FIG. 8. As a slight departure from the notation employed in FIG. 8, the process illustrated in FIG. 12 employs the index n to keep track of the successive frames, and the next target frame F0 is set to Fm while the subsequent frame F1 is set to Fm+1.

The description of this process will now skip to a point at which blending has been completed for a current frame, so that the index n is to be incremented by one: n=n+1. This incrementing of the index n is performed using n=n+1. This incrementing of the index n is performed as part of an increment step of block 85, which begins a new iteration of the cyclic process. In the increment step of block 85, the current time is shifted by tmin, the current target frame F1 is updated to the subsequent frame F2 of the previous iteration and the current target frame Fm is set to the next frame Fm+1 specified by the user. The global velocity v includes both the linear velocity v and the angular velocity ao in accordance with Equation 11. In the increment step of block 85, the initial block velocity v0 is corrected by an error correction global velocity v0 computed in another part of the process in accordance with Equation 65 in a manner described below herein. As will be described, the purpose of this correction is to compensate for a residual error at point b of FIG. 8 corresponding to a blend exit frame Fm+1 specifically the residual error discussed with reference to Equation 63.

Next, a differentiation step of block 90 is performed using a computation described below called framediff to compute a global velocity v1 necessary to move from frame F0 to frame F1 within a time T1, specified by the user. The step of block 90 then computes from the two global velocities v1 and v0 and from a maximum acceleration specified by the user, a blend interval time t0 in accordance with Equation 23, 26 or 29 using a process calctau described later in this specification.

The blending algorithm has also been implemented for real-time control on a 12.5 MHz Heurikon 68020 processor. For the tests, a trajectory similar to the simulation trajectory has been executed. However, since the robot base position is fixed, the size of the inspection area is restricted. A total of twelve via frames are used to scan a rectangular shape about half as large as that in the simulation. Linear blending was arbitrarily chosen for these tests. During experiments the minimum time between frames is 3 seconds. The real-time process runs at 44 Hz, or ~22.7 ms, giving approximately 132 iterations for each frame to frame motion. (The control rate is governed by other control software, not the processing requirements of the trajectory blending algorithm, which we have shown to be quite minimal.) The position gain was $K_p=20$, and the trajectory correction gain was $K_{cor}=0.3$. The minimum blend time was $t_{min} \approx 20$ iterations, or about a half second. The maximum acceleration was $l_{alma}=10$ m/s².
At a decision block 120, a determination is made whether the blend time \( t = T_0 - t_0 \) has been reached. If not (YES branch of block 120), then the current global velocity \( v \) is kept constant at \( v_0 \) (block 125) and the time \( t \) is incremented by adding to it a time differential \( \delta t \) (block 130).

A frame incrementing step 135 is performed using the current angular velocity \( \omega \) of the current global velocity \( v \). This frame incrementing step 135 is a rotation of the manipulator though an incremental angle equal to \( \omega \delta t \). The frame incrementing step of block 135 updates the current frame \( F \). The process then cycles back to the determination step of block 120 and continues in a cycle constituting the steps of blocks 120, 125, 130 and 135. This cycle is repeated until the time \( t \) reaches the blend time \( t = T_0 - t_0 \) (NO branch of block 120).

Once the blend time has been reached, a determination is made at a decision block 140 whether the current time \( t \) falls within the blend time window \( T_0 - t_0 \leq t \leq T_0 - t_0 - To \). If so (YES branch of block 140), then the blend function \( f(t_o) \) is computed (block 145) according to Equation 33, 34 or 35 and this function is used to update the current blended global velocity \( v \) using Equation 16. The current time is incremented in the step of block 150 as in the step of block 130. The frame incrementing step of block 135 is performed, but this time using the current angular velocity \( \omega \) of the global velocity \( v \) blended between \( v_0 \) and \( v_1 \) in accordance with Equation 16 by the step of block 145. The process cycles back to the determination step of block 140. A cycle constituting blocks 140, 145, 150 and 135 is repeated until the time \( t \) exceeds the blend period (NO branch of block 140).

Each iteration of this cycle produces an incremental rotation of the frame using an angular velocity vector to updated each iteration.

Upon completion of this cycle (i.e., when \( t = T_0 - t_0 \)), a sequence of incremental rotations has been performed as depicted in FIG. 8 to blend the manipulator motion from the initial frame \( F_0 \) to the blend exit frame \( F_D \). With each iteration of the process after each time increment \( \delta t \), the frame increment step of block 135 computes an updated frame \( F \) which is output by the trajectory generator 10 of FIG. 11 to the manipulator control system cartesian controller 20 of FIG. 11 to produce a command \( \omega \) to the robot servos to rotate and/or translate the robot manipulator to the updated frame.

Taking the NO branch of block 140, the current frame \( F \) is compared to the desired blend exit frame \( F_D \) (corresponding to point \( b \) of FIG. 8) obtained from a frame incrementing step 105. The frame incrementing step is an incremental rotation by an angle obtained by multiplying the initial angular velocity \( \omega_0 \) by half the blend time, \( \delta t \), obtained from the step of block 90 (Both frame incrementing steps 105 and 135 employ a process called framedef defined later in this specification.)

Then, a differentiation step 110 computes a velocity error correction \( v_e \) by dividing the difference between the current frame \( F \) and the desired blend exit frame \( F_D \) by the time remaining to the next frame, \( T_0 - t_0 \). The incrementing step of block 85 is repeated, and the entire process begins the next iteration with a new target frame \( F_{n+2} \). The adding step \( v_e = v_0 + v_e \) of block 85 compensates for the residual error of the previous blend cycle and implements the correction of Equation 65. (The differentiation steps of both blocks 90 and 110 employ a process called framedef defined later in this specification.)

The foregoing process is now set forth in greater detail as a series of program language statements, each statement being accompanied by an explanatory remark in italics. In the following, there is a main program, called main body which calls for four different sub-routines named, respectively, framedef, framedif, calcult and calcfprime.

9.1 Main Body

BEGIN:

n = 0 initialize counter

F = frameinc(initial desired to current frame)

F = framedif(initial desired to current frame) subsequent frame (if unavailable set to \( F_o \)).

\( v_1 = \text{framedef}(F_0,F) \) determine average velocity needed between frames.

\( t = \text{frameinc} \), initial time

NEXT:

if \( T_0 - t_0 \) constant velocity in leg

\( F = \text{framedef}(F_0,v(1) + St) \) get blend function value

\( v = \text{framedif}(F_0,F) \) calculate blended velocity

END:

9.2 Frame Differencing Subroutine

frameinc\( (F_o,F) \) frame differencing subroutine

\( v = (p_1 - p_0) \) linear velocity assuming unit time

\( \kappa \sin\phi = \frac{1}{2} \left( n_0 \times n_1 + n_0 \times n_1 + n_0 \times n_1 \right) \)

\( \cos\phi = \frac{1}{2} \left( n_0 \times n_1 + n_0 \times n_1 + n_0 \times n_1 - 1 \right) \)

if \( \kappa \sin\phi = 0 \) \{ ambiguous result \}

if \( \cos\phi = 1 \) \{ no difference in frames \}

if \( \cos\phi = -1 \) \{ greatest difference in frames \}

\( \phi = \pi \)

if \( \sin\phi = 0 \) \{ \kappa \sin\phi = 0 \} \}

\( k_e = \sqrt{(n_0 + 1)^2} \)

if \( \kappa(n_0) = 0 \), substitute \( n_0 \), \( n_0 \), \( n_0 \)

\( k_e = n_0 \times k_0 \)

Angular velocity assuming unit time

\( \psi = \psi_1 - \psi_0 \) scalar velocity assuming unit time
9.3 Frame Incrementing Subroutine

\[
\text{frameinc}(F_{0},V_{0},\Delta t) = \text{return frame difference}
\]

\[
\begin{aligned}
\theta &= \omega_{0}/\omega, && \text{rotation angle} \\
\kappa &= \omega_{0}/\omega, && \text{rotation axis} \\
S &= \sin\theta, && \text{sin} \\
C &= \cos\theta, && \text{cos} \\
V &= 1 - \cos\theta
\end{aligned}
\]

\[
R = \begin{bmatrix}
k\Delta_{x}V_{0} + C & k\Delta_{y}V_{0} - k\Delta_{z} & k\Delta_{y}V_{0} + k\Delta_{z} \\
k\Delta_{y}V_{0} + k\Delta_{z} & k\Delta_{z}V_{0} + C & k\Delta_{z}V_{0} - k\Delta_{x} \\
k\Delta_{z}V_{0} - k\Delta_{x} & k\Delta_{x}V_{0} + k\Delta_{y} & k\Delta_{x}V_{0} + C
\end{bmatrix}
\]

rotation matrix

\[
R_{t} = R \cdot R_{0} \quad \text{increment orientation}
\]

\[
p_{t} = p_{0} + \omega_{0} \Delta t \quad \text{increment position}
\]

\[
V_{t} = V_{0} + \Delta V_{0} \quad \text{increment scalar}
\]

\[
\text{return}(F_{t} = \{ R_{t}, p_{t}, V_{t}, \theta_{t} \}) \quad \text{return the new frame}
\]

9.4 Calculation of Blend Time Subroutine

\[
calctau(\Delta v) = \text{calctau}(\Delta v; \Delta \theta_{\text{max}})
\]

\[
\begin{aligned}
\text{if(LINEAR)} & \quad \text{return}(\Delta v/2\Delta \theta_{\text{max}}) \quad \text{linear blending} \\
\text{if(3POLY)} & \quad \text{return}(3\Delta v/4\Delta \theta_{\text{max}}) \quad \text{third order polynomial blending} \\
\text{if(CYCLOID)} & \quad \text{return}(\sin\left(\frac{\pi}{2} \cdot \frac{\Delta v}{\Delta \theta_{\text{max}}}\right)) \quad \text{cycloidal blending}
\end{aligned}
\]

10 Conclusion

This specification has presented a new formulation of trajectory generated based on velocity blending. First, a new formulation for trajectory blending was provided, allowing for the direct comparison and utilization of numerous blend functions. Then, a generalized version of the previously proposed orientation matrix blending formulation was reviewed. It was shown how a first order approximation of this scheme leads directly to angular velocity blending for orientation change. Further, the residual error incurred was explained, quantized, and compensated. Also explained were implementational considerations such as acceleration limits, velocity summation requirements, algorithm computation rates and complexity. Finally, the results of implementation of this scheme in both simulation and real-time experimentation were graphically presented. Both the analysis and implementation has shown that the speed and simplicity of the velocity-blending formulation enable its ease of use for real-time manipulator trajectory generation.

Appendix A contains a listing of a C-language computer code employed in carrying out the invention. Each of the key statements in the listing is accompanied by an explanatory remark in italics.

What is claimed is:

1. A method of controlling a robot manipulator moving toward a target frame $F_0$ with a target velocity $v_0$, comprising a linear target velocity $v$ and an angular target velocity $\omega_0$, to smoothly and continuously divert said robot manipulator to a subsequent frame $F_1$, said target frame being associated with a target transition time $T_0$, and said subsequent frame being associated with a subsequent transition time $T_1$, said method comprising the steps of:

   determining a global transition velocity $v_1$ necessary to move said manipulator from said target frame $F_0$ to said subsequent frame $F_1$, within said subsequent transition time $T_1$, said global transition velocity comprising a linear transition velocity $v_1$ and an angular transition velocity $\omega_1$;

   defining a blend time interval $2T_0$, within which the global velocity of said robot manipulator is to be changed from a global target velocity $v_0$, to said global transition velocity $v_1$, before said blend time interval, said blended global velocity comprising a blended angular velocity $\omega$ and a blended linear velocity $v$.

   (a) computing a blended global velocity $v$ of said manipulator as a blend of said global target velocity $v_0$ and said global transition velocity $v_1$, said blended global velocity $v$ being at least approximately equal to said target global velocity $v_0$ at the beginning of said blend time interval and at least approximately equal to said target global transition velocity $v_1$ at the end of said blend time interval, said blended global velocity $v$ comprising a blended angular velocity $\omega$ and a blended linear velocity $v$;

   (b) rotating said manipulator by an incremental rotation corresponding to an integration of said blended angular velocity $\omega$ over one discrete time segment $\delta t$;

   The method of claim 1 wherein the step of defining a blend time interval comprises computing blended said blend time interval $2T_0$, from said global target and transition velocities $v_0$ and $v_1$, and from a predetermined maximum acceleration to which said motion of said manipulator is to be limited.

3. The method of claim 2 wherein the step of computing said blend time interval comprises dividing a difference between said target global and transition velocities $v_0$ and $v_1$ by said predetermined maximum acceleration.

4. The method of claim 2 further comprising a velocity error correction step carried out about the beginning of said blend time interval, said velocity error correction comprising the steps of:

   determining a desired blend exit frame $F_{0'}$, said step of determining comprising rotating said target frame $F_0$ through a rotation corresponding to an integration of said angular target velocity $\omega_0$ over at least a portion of said blend time interval $2T_0$;

   determining an error correction global velocity $v_e$ required to move from said target frame $F_0$ to said desired blend exit frame $F_{0'}$ within a correction time interval related to said blend time interval; and

   correcting said target velocity by adding to it said error correction velocity.

5. The method of claim 4 wherein said portion of said blend time interval is about half blend time interval.

6. The method of claim 4 wherein said correction time interval is a difference between said target transition time and half blend time interval, $T_0 - T_0/2$.

7. The method of claim 4 wherein the step of determining a desired blend exit frame $F_{0'}$ further comprises translating said target frame $F_0$ by a displacement corresponding to an integration of said linear target velocity $v_0$ over at least a portion of said blend time interval $2T_0$.

8. The method of claim 1 wherein the step of computing a blended global velocity comprises computing a sum of $v_0(1-f) + v_1(f)$, wherein $f$ changes with each time increment $\delta t$.

9. The method of claim 8 wherein $f$ is a function which is approximately zero at the beginning of said blend time interval and is approximately one at the end of said blend time interval to provide linear blending.

10. The method of claim 8 wherein $f$ is a function which provides one of: (a) third order polynomial velocity blending, (b) cycloidal velocity blending.

11. The method of claim 1 further comprising translating said manipulator by an incremental translation corresponding to an integration of said blended linear velocity $v$ over one discrete time segment $\delta t$ during each of said discrete time segments.

12. The method of claim 1 wherein during a preceding time interval immediately prior to said blend time interval said manipulator is maintained at an approximately constant global velocity equal to said target global velocity $v_0$, while performing the following steps:

   (a) computing a blended global velocity $v$ of said manipulator as a blend of said global target velocity $v_0$ and said global transition velocity $v_1$.

   (b) rotating said manipulator by an incremental rotation corresponding to an integration of said blended angular velocity $\omega$ over one discrete time segment $\delta t$.

   (c) correcting said target velocity by adding to it said error correction velocity.

13. The method of claim 12 further comprising translating said manipulator by an incremental displacement corresponding to an integration of said target linear velocity $v_0$ over one discrete time segment $\delta t$.

14. The method of claim 1 further comprising specifying a sequence of successive target frames $F_i$ associated with respective transition times $T_i$, for $i$ between 1 and $n$ wherein $n$ is an integer, and wherein the transition time $T_i$ and said subsequent frame $F_{i+1}$ are associated with a target transition time $T_0$, said target frame being associated with a subsequent transition time $T_{i+1}$, said method comprising the steps of:

   determining a global transition velocity $v_i$, necessary to move said manipulator from said target frame $F_0$ to said subsequent frame $F_i$, within said subsequent transition time $T_i$, said global transition velocity comprising a linear transition velocity $v_i$ and an angular transition velocity $\omega_0$;

   defining a blend time interval $2T_0$, within which the global velocity of said robot manipulator is to be changed from a global target velocity $v_0$, to said global transition velocity $v_1$ and said blend time interval $2T_0$ into discrete time segments $\delta t$; and

   (a) computing a blended global velocity $v$ of said manipulator as a blend of said global target velocity $v_0$ and said global transition velocity $v_1$, said blended global veloc-
ity $v$ being at least approximately equal to said target global velocity $v_0$ at the beginning of said blend time interval and at least approximately equal to said global transition velocity $v_1$ at the end of said blend time interval, said blended global velocity $v$ comprising a blended angular velocity $\omega$ and a blended linear velocity $v$, and

(b) changing an actual global velocity of said manipulator in accordance with said blended angular velocity $\omega$.

16. The method of claim 15 wherein the step of defining a blend time interval comprises computing said blend time interval $\tau_0$ from said global target and transition velocities $v_0$ and $v_1$ and from a predetermined maximum acceleration to which motion of said manipulator is to be limited.

17. The method of claim 16 wherein the step of computing said blend time interval comprises dividing a difference between said global target and transition velocities $v_0$ and $v_1$ by said predetermined maximum acceleration.

18. The method of claim 16 further comprising a velocity error correction step carried out about the beginning of said blend time interval, said velocity error correction comprising the steps of:

- determining a desired blend exit frame $F'_0$, said step of determining comprising rotating said target frame $F_0$ through a rotation corresponding to an integration of said angular target velocity $\omega$ over at least a portion of said blend time interval $2\tau_0$;
- determining an error correction global velocity $v_e$ required to move from said target frame $F_0$ to said desired blend exit frame $F'_0$ within a correction time interval related to said blend time interval, and correcting said target velocity by adding to it said error correction velocity.

19. The method of claim 18 wherein said portion of said blend time interval is about half said blend time interval.

20. The method of claim 18 wherein said correction time interval is a difference between said target transition time and half said blend time interval, $T_P-\tau_0$.

21. The method of claim 15 wherein the step of computing a blended global velocity comprises computing a sum of $v_0(1-f)+v_1(f)$, wherein $f$ changes with each time increment $\delta t$.

22. The method of claim 21 wherein $f$ is a function which provides one of: (a) third order polynomial velocity blending, (b) cycloidal velocity blending.
