Received: November 6, 1995; In Final Form: January 2, 1996

Rate coefficients for the reaction C₂H + CH₄ → C₂H₂ + CH₃ and C₂H + CD₄ → C₂HD + CD₃ are measured over the temperature range 154–359 K using transient infrared laser absorption spectroscopy. Ethynyl radicals are produced by pulsed laser photolysis of C₂H₂ in a variable temperature flow cell, and a tunable color center laser probes the transient removal of C₂H (X³Σ⁺ (0,0,0)) in absorption. The rate coefficients for the reactions of C₂H with CH₄ and CD₄ both show a positive temperature dependence over the range 154–359 K, which can be expressed as k_C₂H/CH₄ = (1.2 ± 0.1) × 10⁻¹⁰ exp[(-491 ± 12)/T] and k_C₂H/CD₄ = (8.7 ± 1.8) × 10⁻¹² exp[(-650 ± 61)/T] cm³ molecule⁻¹ s⁻¹, respectively. The reaction of C₂H + CH₄ exhibits a significant kinetic isotope effect at 300 K of k_C₂H/CH₄ = 2.5 ± 0.2. Temperature dependent rate constants for C₂H + C₂H₂ were also remeasured over an increased temperature range from 143 to 359 K and found to show a slight negative temperature dependence, which can be expressed as k_C₂H/C₂H₂ = 8.6 × 10⁻¹⁰ T⁻¹.8 exp[(474 ± 90)/T] cm³ molecule⁻¹ s⁻¹.

Introduction

This work is part of an ongoing project to measure, for the first time, low-temperature rate constants of the C₂H radical with various hydrocarbons present in Titan’s atmosphere. In planetary atmospheres, such as Titan’s, the ethynyl radical can catalyze the dissociation of CH₄ to form methyl radicals, CH₃.

\[ \text{C}_2\text{H}_2 + h\nu \rightarrow \text{C}_2\text{H} + \text{H} \]  
(1)

\[ \text{C}_2\text{H} + \text{CH}_4 \rightarrow \text{C}_2\text{H}_2 + \text{CH}_3 \]  
(2)

net \[ \text{CH}_4 \rightarrow \text{CH}_3 + \text{H} \]  
(3)

The recombination of two methyl radicals produces ethane, C₂H₆, which can be transported downward to the moon’s surface. Hence, the reaction C₂H + CH₄ is of central importance in photochemical models of Titan to understand why ethane is so abundant in Titan’s atmosphere.¹ ²

This is the first low-temperature study of the reactions

\[ \text{C}_2\text{H} + \text{CH}_4(\text{CD}_4) \rightarrow \text{C}_2\text{H}_2(\text{C}_2\text{HD}) + \text{CH}_3(\text{CD}_3) \]  
(4)

over the temperature range 154–359 K. A complete study of the reaction C₂H + C₂H₂ from 170 to 350 K, another critical reaction in Titan’s atmosphere, was already reported by this laboratory.³ here, these measurements have also been extended to 143–359 K. Low-temperature rate constants of reaction 4 will help decide which reaction schemes for ethane production are consistent with data from Voyager IRIS (infrared interferometer spectrometer) results.⁴ ⁵ In addition, NASA plans to launch a mission called Cassini, which is intended to study Saturn and its moon Titan some time in 1996. The rate coefficients measured in this experiment will be used to model Titan’s atmosphere to compare calculated gas densities with measured concentrations from the Cassini mission. In addition, these results provide an experimental basis for theoretical studies on primary isotope effects.

Experimental Technique

Briefly, the kinetics of C₂H + CH₄ and CD₄ are studied using transient infrared laser absorption spectroscopy. A schematic of the experimental setup is shown in Figure 1. The low-temperature kinetics measurements are described in detail in an earlier paper.⁶ The only significant change was to add Brewster windows to the flow cell to incorporate a multipass arrangement for the probe laser beam to increase the absorption path length.

Ethynyl radicals are produced in the meter long variable temperature flow cell by a pulsed excimer laser at 193 nm. The excimer laser was operated at 55 mJ/pulse at a repetition rate of 10 Hz. Acetylene has an absorption cross section of 1.35 × 10⁻¹⁹ cm² at 193 nm⁷ and a quantum yield of approximately 0.26 for C₂H production.⁸ After accounting for UV laser loss on the windows and absorption in air, the C₂H concentration was calculated to be no greater than 4.6 × 10⁻¹⁰ cm⁻³ for the highest acetylene pressures (the acetylene number density was...
Low-Temperature Rate Coefficients of C2H with CH4 and CD4

The experiments involving just the reaction \( \text{C}_2\text{H} + \text{C}_2\text{H}_2 \), the color center is running on one longitudinal mode, and a scanning Fabry-Perot spectrum analyzer is used to ensure that the transient concentration of ethynyl radical in absorption can be neglected since the time between collisions for \( \text{C}_2\text{H} \) and \( \text{C}_2\text{H}_2 \) is always present. Contributions from radical-radical reactions can be neglected since the time between collisions of \( \text{C}_2\text{H} \) and \( \text{CH}_4 \) is 1000 times longer at the highest \( \text{C}_2\text{H} \) density than can be neglected since the time between collisions for two \( \text{C}_2\text{H} \) radicals. The transverse flow arrangement in the cell allows high laser repetition rates with minimal photolysis of the same gas volume. With typical linear flow rates of 1.9 \( \times 10^{20} \) molecules s\(^{-1} \), about 90% of which is helium, the photolysis volume is replenished every 10 laser pulses. Kinetic experiments are performed at various methane (methane-d) densities (\( 0.2-2.5 \) \( \times 10^{17} \) cm\(^{-3} \)). The total helium density is in the range (1.6-6.4) \( \times 10^{14} \) cm\(^{-3} \) in the \( \text{CH}_4 \) (CD\( _4 \)) experiments. For these experiments a 1000-1500-fold excess of \( \text{CH}_4 \) (CD\( _4 \)) with respect to \( \text{C}_2\text{H}_2 \) is always present. Contributions from secondary or radical-radical reactions can be neglected since the time between collisions for \( \text{CH}_4 \) and \( \text{CD}_4 \) (CD\( _4 \)) is 1000 times shorter than the time between collisions of two \( \text{C}_2\text{H} \) radicals. The transverse flow arrangement in the cell allows high laser repetition rates with minimal photolysis of the same gas volume. With typical linear flow rates of 1.9 \( \times 10^{20} \) molecules s\(^{-1} \), about 90% of which is helium, the photolysis volume is replenished every 10 laser pulses. Kinetic experiments are performed at various methane (methane-d) densities (\( 0.2-2.5 \) \( \times 10^{17} \) cm\(^{-3} \)). The total helium density is in the range (0.4-2.4) \( \times 10^{18} \) cm\(^{-3} \), and the methane density is held at 0.7 \( \times 10^{17} \) cm\(^{-3} \) to test for a pressure dependence. In the experiments involving just the reaction \( \text{C}_2\text{H} + \text{CH}_4 \), the acetylene number density was in the range (0.2-6.0) \( \times 10^{15} \) cm\(^{-3} \), and the helium number density was in the range (0.32-3.2) \( \times 10^{18} \) cm\(^{-3} \). For the highest acetylene pressures, the \( \text{C}_2\text{H} \) concentration is estimated to be no greater than 6.7 \( \times 10^{14} \) cm\(^{-3} \). Therefore, a 300-9000-fold excess of \( \text{C}_2\text{H}_2 \) with respect to \( \text{C}_2\text{H} \) is always present. Contributions from radical-radical reactions can be neglected since the time between collisions for two \( \text{C}_2\text{H} \) radicals is 1000 times longer at the highest \( \text{C}_2\text{H} \) density than the time between collisions for \( \text{C}_2\text{H} \) and \( \text{CH}_4 \).

A high-resolution color center laser tuned to the Q\( _{11}(9) \) line at 3593.68 cm\(^{-1} \) of the A \( ^2\Pi \rightarrow X \ ^2\Sigma \) transition probes the transient concentration of ethynyl radical in absorption. A scanning Fabry-Perot spectrum analyzer is used to ensure that the color center is running on one longitudinal mode, and a home-built scanning Michelson interferometer wavemeter is used to monitor the color center's wavelength.

The probe beam, after three to five multipasses, is directed onto a 50-MHz 77 K Ge:Au detector which has a 20-mm\(^2 \) sensitive area. The transient signals are amplified and then coadded using a 100-MHz digital oscilloscope. Typical single-shot traces have a signal-to-noise ratio of 20-30. For a typical run, transient signals from 1000 excimer pulses are averaged. The amplitude of the transient \( \text{C}_2\text{H} \) signal is found to be linear with color center probe power.

In all experiments, acetylene, helium, and methane or methane-d\( _4 \) were flowed through a mixing cell before entering the reaction cell. Helium is used to thermally equilibrate the mixture with the cell walls. In earlier experiments, sulfur hexafluoride, SF\( _6 \) was used to vibrationally and electronically quench the \( \text{C}_2\text{H} \) this was omitted from this study because it was found to have no effect on the relatively slow ground-state removal rates, as discussed below. All gases are obtained commercially with the following purities: He, 99.99%; \( \text{C}_2\text{H}_2 \), 99.6%; \( \text{CH}_4 \), 99.99%; CD\( _4 \), 99.6%. The acetone in the \( \text{C}_2\text{H}_2 \) is removed by passing the gas through an activated charcoal filter. Partial pressures of each gas are determined by calibrated mass flow meters and the measured total pressure inside the cell. With the use of isopentane as a cooling solvent, temperatures as low as 143 K can be reached. For measurements taken above 300 K, heated water was used as the solvent.

Analysis of Kinetic Data

In this study we observe reactions from the ground state of \( \text{C}_2\text{H} \ (X^2\Sigma^+ \ (0,0,0)) \) directly. For accurate measurements it is necessary that the electronic and vibrationally excited states of \( \text{C}_2\text{H} \) be fully quenched. Work done by Glass et al. under similar conditions reports that relaxation of the \( \text{C}_2\text{H} \ (X(0,0,1)) \) state occurs in approximately 1 \( \mu \)s. Therefore, if sufficient time has elapsed, complete vibrational and electronic relaxation should have occurred before any ground-state measurements are made. The data is fit only beginning with times a factor of 3 longer than the rise time to ensure complete relaxation of upper vibrational states of \( \text{C}_2\text{H} \). In previous studies SF\( _6 \) was used as a vibrational quencher. Temperature dependent measurements with and without SF\( _6 \) were taken, and the measured rate constants were found to be equal. Therefore, SF\( _6 \) was not used for this study.

Prior to measuring rate coefficients for the reaction \( \text{C}_2\text{H} + \text{CH}_4 \) (CD\( _4 \)), an accurate temperature dependence investigation of the rate constant for

\[
\text{C}_2\text{H} + \text{C}_2\text{H}_2 \rightarrow \text{C}_2\text{H}_2 + \text{H} \tag{5}
\]

had to be completed. Earlier measurements could only be made down to 170 K, and here it was desired to extend the results to at least 143 K. The experiments were done under pseudo-first-order conditions where \( \text{[C}_2\text{H}_2] \gg \text{[C}_2\text{H}] \) by a factor of 500-1500. The rate equation for reaction 5 integrates to

\[
[C_2\text{H}] = [C_2\text{H}]_0 \exp(-k_\text{obs} t) \tag{6}
\]

where

\[
k_\text{obs} = k_{\text{C}_2\text{H}_2} [\text{C}_2\text{H}_2] \tag{7}
\]

The observed rate coefficients, \( k_\text{obs} \), are calculated by fitting the observed decay traces to a single-exponential decay plus a constant, eq 8, to fit the zero level of the base line

\[
y = A \exp(-k_\text{obs} t) + \text{constant} \tag{8}
\]
where \(A\) is the pre-exponential factor, \(t\) is the time, and \(k_{\text{obs}}\) is the observed rate coefficient; see Figure 2. The fits for \(k_{\text{obs}}\) are then plotted against their respective \([C_2H]\) concentrations, and the gradient is \(k_{C_2H}\); see Figure 3. The uncertainty in \(k_{C_2H}\) is calculated on the basis of the uncertainties in fitting \(k_{\text{obs}}\), measuring \([C_2H]\), and measuring the temperature. This leads to relative errors in \(k_{C_2H}\) of 10–13%, depending on the temperature.

Table 1 is a summary of the rate constants measured for \(C_2H + C_2H_2\) down to 143 K. The data from ref 3 and the new data can be fit approximately to the Arrhenius equation. However, the data is best fit by the equation

\[
[C_2H]/[C_2H]_0 = \exp(-k_{\text{obs}}t) \]  

and

\[
k_{\text{obs}} = k_{\text{CX}_4}[\text{CX}_4] + k_{\text{C}_2\text{H}_2}[\text{C}_2\text{H}_2] \]  

0.2) x 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1} \) cm. One obtains a value for \(k_{\text{obs}}\) of 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1} \), which can be expressed as

\[
d[\text{C}_2\text{H}]/dt = -[\text{C}_2\text{H}](k_{\text{CX}_4}[\text{CX}_4] + k_{\text{C}_2\text{H}_2}[\text{C}_2\text{H}_2]) \]  

Using the present value of \(k_c\), one obtains a value for \(k_{\text{obs}}\) of 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1} \). Okabe photolyzed \(C_2H_2\) at 14 K and determined a ratio of \(k_{C_2H}/k_{C_2H_2} = 0.032 \pm 0.001\). Hence, the reaction \(C_2H + CD_4\) exhibits a significant kinetic isotope effect at 300 K of \(k_{C_2H}/k_{CD_2} = 2.5 \pm 0.2\).

**Discussion**

Previous measurements of the reaction \(C_2H + CH_4\) were performed at room temperature and are summarized in Table 3. Rerdlund et al. monitored the CH (A-X) product chemiluminescence from the \(C_2H + O_3\) reaction with and without \(CH_4\). They measured a room temperature value of \(k_{CH_4} = (4.8 \pm 1.0) \times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1} \), and determined a ratio of \(k_{CH_4}/k_{C_2H_2} = 0.032 \pm 0.001\). Using the present value of \(k_{C_2H_2}\) at room temperature of \(1.3 \times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1} \), one obtains a value for \(k_{C_2H}\) of \(4.2 \times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1} \). Lauer photolysed...
Low-Temperature Rate Coefficients of C_2H with CH_4 and CD_4

The rate constants for the reaction C_2H + CH_4 at 300 K and from 227 to 359 K are equal to (3.1 ± 0.1) × 10^{-12} and (5.2 ± 0.6) × 10^{-13} cm^3 molecule^{-1} s^{-1}, respectively. From the Arrhenius fit, the energy of activation for C_2H + CH_4 is equal to 4.3 ± 0.1 kJ mol^{-1}. Rate coefficient measurements for C_2H + CD_4 at 300 K and from 227 to 359 K result in a k_{CD_4} = (0.9 ± 0.1) × 10^{-12} and k_{CD_4} = (8.7 ± 1.8) × 10^{-12} cm^3 molecule^{-1} s^{-1}, respectively. The energy of activation for C_2H + CD_4 from 227 to 359 K is equal to 5.4 ± 0.5 kJ mol^{-1}. No pressure dependence was found for k_{CD_4} at 300 K over the experimental range (0.4-2.4) × 10^{18} cm^{-3}. Over this number density range, there was no temperature dependence over 170-350 K. More recent results by Van Look et al. also showed no evidence for a temperature dependence from 295 to 450 K. They measured rate coefficients of the reaction C_2H + O_2 by monitoring CH^+ emission. Okabe measured k_{CH^+} = 0.032 ± 0.0018. This leads to a value of k_{CH^+} that is ~2 times faster at room temperature than the k_{CH^+} reported in this work when using (1.3 ± 0.2) × 10^{-10} cm^3 molecule^{-1} s^{-1} for k_{CH^+}. Okabe’s result involved measuring the quantum yield ratio of diacetylene without (ψ_o(2H_2)) and with (ψ_2(2H_2)) CH_4 in the mixture and not a direct measurement of the reaction of C_2H with CH_4.

The work presented here on C_2H + C_2H_2 further supports the reasoning that C_2H_2 is formed via an addition mechanism with no barrier to formation. The short-lived intermediate then immediately dissociates to C_2H_2 + H. A previous study on C_2H + C_2H_2 by this lab reported that within experimental error there was no temperature dependence over 170–350 K. More recent results by Van Look et al. also showed no evidence for a temperature dependence from 295 to 450 K. They measured rate coefficients of the reaction C_2H + O_2 by monitoring CH^+ emission. The rate coefficients for C_2H with C_2H_2 were taken from the k’ versus [O_2] plots. An Arrhenius fit to their data is reported as k’ = (1.3 ± 0.2) × 10^{-10} cm^3 molecule^{-1} s^{-1}. Despite previous measurements for the rate coefficients of C_2H + C_2H_2, which show no definite temperature dependence above room temperature, new data presented in this study...
does reveal a small negative temperature dependence in the rate coefficients for C\textsubscript{3}H + C\textsubscript{2}H\textsubscript{3}.

The measured kinetic isotope effect at 300 K is \( k_{\text{CH}}/k_{\text{CD}} = 2.5 \pm 0.2 \). Unfortunately, no transition-state calculations have been done on this reaction to be able to compare theory with experiment. Judging by the magnitude of the isotope effect and the reaction mechanism involved, the reaction C\textsubscript{3}H + CH\textsubscript{4} (CD\textsubscript{4}) exhibits a large primary isotope effect in which the main contribution is the difference in zero-point energies between the initial states and the transition states.\textsuperscript{18-20} Hopefully this research will encourage theoretical studies of C\textsubscript{3}H + CH\textsubscript{4} (CD\textsubscript{4}) for comparison.

In addition to the kinetic isotope effect, there is the possibility for tunneling to occur in this reaction between the H (D) atom of methane and the carbon atom of the C\textsubscript{3}H radical. Unfortunately, no curvature is detected in the Arrhenius plot over 154-359 K. This does not eliminate the possibility of tunneling taking place. If the experiment could be done over a larger temperature range, the possibility of detecting curvature in the Arrhenius plot would be more favorable.

Results based on the effect of reaction 2 on photochemical models of Titan are forthcoming. There is little question that this reaction plays a key role in determining the ethane concentration on Titan, but recent experiments by Mordaunt et al.\textsuperscript{21} have uncovered a new CH\textsubscript{4} photolysis channel that will affect current photochemical models. Mordaunt et al. have shown that the direct photodissociation of CH\textsubscript{4} to CH\textsubscript{3} + H is the main source of methyl radicals in Titan’s atmosphere. Both the discovery by Mordaunt et al. and the data in this work should help to clarify the production of ethane in Titan’s atmosphere. Updated versions\textsuperscript{2} of the Yung et al. model and more low-temperature rate coefficients of pertinent reactions are needed to determine whether a complete analysis will match forthcoming spacecraft observations.
