Summary Report (1996-97) and Request for Renewal (1997-98)

Abstract

This document summarizes the progress we have made on our study of issues concerning the schedulability of real-time systems. Our study has produced several results in the scalability issues of distributed real-time systems. In particular, we have used our techniques to resolve schedulability issues in distributed systems with end-to-end requirements. During the next year (1997-98), we propose to extend the current work to address the modeling and workload characterization issues in distributed real-time systems. In particular, we propose to investigate the effect of different workload models and component models on the design and the subsequent performance of distributed real-time systems.

1 Introduction

The stringent demands to guarantee task deadlines in real-time systems have motivated both practitioners and researchers to look ways to analyze systems prior to run-time. In our study, a new perspective of analyzing real-time systems that can guarantee meeting the deadline guarantees as well as qualify the guarantees. We express the qualification of the deadline guarantees through a scaling factor. In simple terms, the scalability factor enables one to decide by how much the execution time of each of the subtasks in a distributed task be increased still retaining the deadline meeting guarantees.
In this work, we have solved several scheduling problems using the scalability factor. Following is a summary of the results. The details of the work are in the appendix [1, 2, 3].

2 Summary of Work done during 1996-97

The results from our work on scalability based admission control [3] can be summarized as follows:

- Two heuristics were developed using scalability factor. Heuristic 1, referred to as $R$, uses non-optimal low-cost computation of the scalability factors. Heuristic 2, referred to as $S$, uses an optimal computation of the scalability factors.

- For low utilizations, we observe that both heuristics have similar admissibility. Given that $R$ is less expensive than $S$, we recommend that the former be used under low utilizations.

- For a given value of number of channels and a given tightness of the deadlines, we observe that the admissibility of $R$ falls abruptly beyond a certain utilization factor. So $R$ should be used only when the utilization is lower than this bound.

- The performance of $S$, however, degrades gracefully beyond the utilization bound. Hence, this has a better resilience to utilization than $R$.

- As the number of channels increases, the success of heuristic $S$ improves compared to $R$.

- $S$ has better performance with respect to rejecting inadmissible channels compared to $R$. Thus $S$ is to be preferred when the cost of accepting inadmissible channels is high.

The results from our work on scalability in real-time systems with end-to-end requirements [1] has the following conclusions:

- We have identified several issues of concern that researchers and practitioners face during the design, development, and maintenance of complex real-time systems.
• We have shown that the questions posed by these issues can be formulated from two viewpoints: component changes and task changes.

• We reduced the above two problems to two fundamental problems, viz., a schedulability of a task-set with arrival times and its scalability.

• We have presented optimal solutions to the two problems.

The PhD thesis [2] summarizes much of the work done during the last four years. It illustrates in a great detail the results obtained in scalability of uniprocessor systems, schedulability of task-sets with specified arrival times, and the scalability in distributed systems with end-to-end deadlines. The techniques developed have been illustrated by taking data from Olympus Attitude and Orbital Control System. The significant contributions of the thesis are summarized as follows.

• We have addressed the need to handle complexity in real-time systems in all phases, viz., design, development, and maintenance.

• We have presented a novel perspective to analyzing real-time systems that in addition to ascertaining the ability of a system to meet task deadlines also qualifies these guarantees.

• The need to qualify guarantees was shown to arise from several scenarios such as scaling application requirements, inaccuracies in task execution time estimations, and porting applications from one platform to another.

• We presented an application of the scaling factor problem in the context of real-time communications. We considered the problem of admission control of real-time channels.

3 Proposed Work During 1997-98

In the 1997-98 period, for which we are now seeking funding, we propose to extend our current research on the following issues.

1. How does component modeling effect the end-to-end scheduling in distributed real-time systems? In particular, we wish to look at the micro elements such as the memory/cache modeling and
the macro elements such as the networks. As a result of this work, we should have a better understanding of the impact of modeling on the design of these systems. Does complex models mean better designs?

2. How does traffic characterization impact the design and analysis of distributed real-time systems? This issue has close relationship with the component modeling discussed above. For example, if we are considering the memory/cache system, what are different traffic characterizations of the incoming reference pattern? Does this characterization greatly affect the design and analysis where it is often used? Once again, we expect to develop several traffic models at different components (or sources) in a distributed system. We shall evaluate their suitability in different applications.

3. Since jitter in response time is of particular concern to several real-time applications such as multimedia and control applications, how accurately can the end-to-end jitter be predicted or controlled? We are especially interested in using this information at the design stage. This step will use the results from the earlier two steps.

1. AIMS AND SCOPE OF THE JOURNAL
Journal of Systems Architecture is a journal covering all aspects of systems architecture design and implementation. It ranges from the microarchitecture level via the system software level up to the application-specific architecture level. Aspects such as dedicated systems, high-performance systems, parallel and distributed architectures as well as additional subjects in the computer and systems architecture area will fall within the scope of this journal. Hardware as well as software design techniques, tools, and performance evaluation techniques will be discussed insofar as they are central to the digital architecture design process. Technology will not be a main focus, but its use and relevance to particular designs will be.

2. CONFERENCE REPORTS AND CALENDAR OF EVENTS
Program chairmen and organizers of major international conferences who wish their conference to be featured in this journal, are invited to contact: Ms. Eefke Smit, Elsevier Science B.V., Mathematics, Computer Science and Cognitive Science Section, P.O. Box 103, 1000 AC Amsterdam, The Netherlands.
Tel.: 31-20-4852473, fax: 31-20-4852616, email: e.smit@elsevier.nl

3. AUTHOR INFORMATION
Contributions (written in English) should be sent in four copies to one of the Editors-in-chief. Manuscripts must contain a compact summary (maximally 150 words) and the full postal address (including email/fax) of all authors. Electronic submissions (accompanied by a paper printout and the original figures) are welcome. The Editors-in-chief will arrange that the paper is transmitted to the appropriate sub-editor who will then begin the review process. A style manual for prospective authors is available on request.
Authors’ benefits:
1. 30% discount on all book publications of North-Holland.
2. 50 reprints are provided free of charge to the principal author of each paper published.

4. THE EUROMICRO ASSOCIATION
Membership of the Euromicro Association includes a personal subscription to the journal. The membership fee for 1996 is Dfl. 125. Membership subscriptions are for personal use only, and should not be made available to libraries or circulated within institutions (e.g., commercial companies).
All persons active in the field of systems architecture are strongly encouraged to become members of Euromicro or else contribute to the journal. Membership benefits include a personal subscription to the journal, reduced fees at the yearly Euromicro symposium and other professional events within the European countries. In addition, Euromicro members will receive timely announcements of events of interest to them in their country. To receive a free information leaflet about the Euromicro Association or to become a member, write directly to: EUROMICRO, P.O. Box 2346, NL-7301 EA Apeldoorn, The Netherlands, or else contact any of the editors.

5. PUBLICATION INFORMATION
JOURNAL OF SYSTEMS ARCHITECTURE (ISSN 1383-7621/0165-6074). For 1996 volume 42 is scheduled for publication.
Subscription prices are available upon request from the publisher. Subscriptions are accepted on a prepaid basis only and are entered on a calendar year basis. Issues are sent by surface mail except to the following countries where air delivery via SAL is ensured: Argentina, Australia, Brazil, Canada, Hong Kong, India, Israel, Japan, Malaysia, Mexico, New Zealand, Pakistan, PR China, Singapore, South Africa, South Korea, Taiwan, Thailand, USA. For all other countries airmail rates are available upon request.
Claims for missing issues must be made within six months of our publication (mailing) date. Please address all your requests regarding orders and subscription queries to: Elsevier Science B.V., Customer Support Department, P.O. Box 211, 1000 AE Amsterdam, The Netherlands. Fax: 31-20-4853432.
Scalability in real-time systems with end-to-end requirements

Abstract

The stringent demands to guarantee task deadlines in real-time systems have motivated both practitioners and researchers to look at ways to analyze systems prior to run-time. This paper reports a new perspective of analyzing real-time systems that in addition to ascertaining the ability of a system to meet task deadlines also qualifies these guarantees. The guarantees are qualified by a measure (called the sealing factor) of the system's ability to continue to provide these guarantees under possible changes to the tasks. This measure is shown to have many applications in the design (task execution time estimation), development (portability and fault tolerance) and maintenance (scalability) of real-time systems. The derivation of this measure in end-to-end systems requires that we solve two fundamental problems - the uni-processor schedulability problem and the uni-processor scalability problem. The uni-processor schedulability problem involves finding whether a set of tasks (with arbitrary non-zero arrival times) will meet its deadlines. The scalability problem seeks to find the maximum scaling factor with which the execution times of a set of tasks can be scaled without invalidating its schedulability. Optimal solutions to these two fundamental problems are presented.

Keywords: Real-time systems; Schedulability; Scalability; End-to-end; Distributed systems

1. Introduction

A real-time system can be characterized by two important components: the environment in which the system is operating and the computer system that controls/monitors the environment. The main issues in the design of the first component concern interfacing with the environment [11]. Solutions in this area are primarily dictated by the technology. There are many issues of concern in the design of the second component, the computer system. The computer system involves both the hardware and the software that runs on them. The choice of hardware is dictated primarily by such parameters as cost/availability and the application at hand. The primary issue in the software design is not so much, the particular choice of language or programming paradigm as it is the way the various tasks are scheduled.

are based on the critical instant argument, which defines a worst-case condition for a task. According to this argument, a task suffers its worst completion time when it has to compete for the processor with every higher priority task in the system. That is, when it arrives at a time when all other higher priority tasks also arrive. This instant is called the critical instant. Accordingly, it is sufficient to look at the completion time of this one instance in order to ascertain the tasks schedulability. But does this computation really give us the worst-case completion time of a task? In other words given a task’s characteristics, will it ever suffer this completion in reality? Notice that the critical instant argument clearly ignores the arrival information of tasks and makes the assumption that for a given arrival (relative to other tasks) of a task, sooner or later (one of its instances) it will meet a critical instant. It can be seen however that, this is not necessarily true and the actual worst-case completion time of a task can be less than or equal to the completion time computed by the critical instant assumption. Therefore, ignoring the arrival times of tasks and using the critical instant argument leads to a pessimistic computation.

Can we tolerate the pessimism inherent to this computation? The answer to this question depends on the environment under consideration, viz., a uni-processor or a distributed (more generally end-to-end) system. In uni-processor systems, depending on the assumptions (task independence for example) made, practitioners [10] have argued that the cost of finding a more precise measure of the task completion time far outweighs the benefit gained (say, in terms of saved resource utilization). However, there are convincing arguments to the contrary by Tindell in [7]. He discusses scenarios that show the importance of considering the task arrival information in schedulability analysis. We believe that the importance can be really felt in end-to-end systems and not so much in uni-processor systems.

Recall from the previous section that the schedulability of a task in an end-to-end system can be reduced to a sequence of uni-processor schedulability problems provided we are able to compute the characteristics (period and arrival time) of the sub-tasks. Let us assume for now that we have a mechanism to compute the sub-task periodicities (the mechanism will be described in detail later). We do not require the arrival time information by the critical instant argument, since we are going to ignore it anyway. We can use the critical instant argument (ignoring the arrival time a_{ik}) to find the worst case completion times of all sub-tasks T_{ik} (1 \leq k \leq m). Clearly, the worst case completion time of the task T_i is given by the sum of the worst-case completion times computed above. Observe that we have a cumulative measure of pessimistic computations that is bound to be more pessimistic.

Before we give a description of the problem we are interested in addressing in this paper, we would like to motivate the reader by briefly discussing the source of the problem. In the previous section we mentioned that the kinds of changes (that interest us) that systems undergo manifest themselves as task execution time changes. A brief discussion of these changes follows.

The task parameters, deadline and periodicity are dictated primarily by the environment. The arrival time of a task is governed by the environment and the inter-dependence between the tasks. The execution time of a task on the other hand is governed among other things by: (1) the programming language chosen, (2) the compiler, (3) the operating system, and (4) the processor architecture (e.g., pipeline, cache). Therefore, finding the execution times of tasks is complex and involved. In most cases it is almost impossible to compute a deterministic measure of the execution time of a task. Most research efforts use the worst-case task execution time and not the mean execution time. While this choice can be justified by the fact that the analysis is based on the worst-case scenario, it nevertheless results in an over-design of the system. Also, this assumption can result in poor resource utilization.
• Arrival time of the task, $a_i$.
• The periodicity of the task, $p_i$.
• The deadline of the task, $d_i$. The deadline is assumed to be less than or equal to the period ($d_i \leq p_i$). In other words, an instance of a task has to be completed before its next instance is ready.
• The execution times of the $m$ sub-tasks (corresponding to the $m$ components in the system), $T_{i1}, T_{i2}, \ldots, T_{im}$: $e_{i1}, e_{i2}, \ldots, e_{im}$. In this model we assume that a component is used only once by a sub-task; relaxing this assumption complicates the model without adding any quality to the results that can be derived. If any task $T_j$ does not have a sub-task on a particular component $R_k$ then, the corresponding sub-task’s ($T_{jk}$) execution time $e_{jk}$ is zero.
• Priority of task, $Pr_i$. We assume that all sub-tasks belonging to a task inherit the task’s priority. This assumption can be easily relaxed without affecting the results reported in this paper. For convenience in representation, we assume that the tasks are ordered (indexed) according to their priority, i.e., $T_1$ is the highest priority task and the priority decreases with the index.

The above notation can also be used to capture a task-set in a single component system, for example, the uni-processor system. If we restrict the number of components, $m$ to be 1, we have each end-to-end task $T_i$ comprising of a single sub-task $T_{i1}$. Further the other parameters, arrival time, period and deadline of the task are also those of the sub-task. In such a scenario we drop the subscript describing the component.

4. Problem statement and description

The problem we are interested in solving is the "Scalability of task-sets in end-to-end real-time systems". The problem can be looked at from two different viewpoints: (1) The first viewpoint stems from assuming the scaling to occur as a result of a change in one or more of the components in the system; and (2) the second viewpoint stems from assuming the scaling to occur as a result of a change in the functionality of some or all of the sub-tasks in the system.

4.1. Component change

A change in a component $R_r$ can result in a gain (no adverse affect on schedulability) or a loss (adversely affects schedulability) in the speed of processing for the sub-tasks running on it. The problem of interest therefore is, to find the maximum factor by which all the sub-tasks on a particular component $R_r$ can be scaled such that the schedulability of the task-set (comprising all $n$ tasks that is) is unaffected.

In the following formulation we assume that a single component is undergoing a change. We can however, generalize it to a sub-set of components. The problem of scaling occurring as a result of a component change can now be formally posed as:

**Problem 1.** Given a task-set $T$ of $n$ end-to-end tasks executing in a system of $m$, $(m \geq 1)$, components, find the optimal scaling factor $1/sfc$ (corresponding to a maximum $sfc$) with which the processing speed of a given component $r$ can be scaled (down), without affecting the schedulability of the task-set.

In other words, we are interested in the maximal component change the taskset can survive. The reason for representing the scaling factor as a reciprocal is obvious once we realize that a lowering in processing speed of a component will reflect as an increase in the execution times of sub-tasks running on the component. For example, if the speed of the component is $S$ (instructions per unit time) then an execution time requirement of a sub-task $T_{ik}$ being $e_{ik}$ (time units) implies that the number of instructions that the sub-task requires to execute are $S \times e_{ik}$. If the processing speed is scaled down by $1/sfc$
The periodicity of all sub-tasks $T_{jk}$, $j \leq i$, which are of higher priority than $T_{ik}$ and are running on the same component $R_k$.

Therefore, we need a mechanism by which we can derive these two parameters (since these are not given a priori). Note that, only the first sub-task of any task is truly periodic. The arrivals of the consecutive instances of any sub-task $T_{ik}$, $1 \leq i \leq n$, $1 \leq k \leq m$, are dictated by the completion times of the sub-task preceding it, i.e., $T_{i,k-1}$. These completions are obviously non-periodic and so are the arrivals of sub-task $T_{ik}$. We however can impose a periodicity on these sub-tasks by a proper justification. The phase adjustment mechanism [3], is one such mechanism that derives sub-task arrival times and also their periodicities. The term phase here is used to denote arrival time.

Imposing a period on the arrivals (of consecutive instances that is) of a sub-task $T_{ik}$, $1 \leq k \leq m$, implies that, even if the preceding sub-task $T_{i,k-1}$ does finish at a particular time $F_{i,k-1}$, the sub-task $T_{ik}$ will not be ready immediately. A finite amount of time (say $W_{i,k-1}$) has to elapse before the sub-task $T_{ik}$ is ready to execute. It is necessary to limit this finite amount of wait time in the sense that, if it is too large then it could hurt the utilization of the component $R_k$. On the other hand this delay must be large enough to be able to accommodate all possible finish times (of its various instances) of task $T_{i,k-1}$. Clearly, therefore, in the limiting condition (delay = 0) $W_{i,k-1}$ must be given by the worst-case completion time of the sub-task $T_{i,k-1}$.

An effect of this adjustment is that a sub-task $T_{ik}$ will always be ready (or arrive) after a constant amount of time from the arrival of the preceding sub-task $T_{i,k-1}$. Therefore, knowing the arrival time of the sub-task $T_{ij}$, we can find the arrival of the sub-task $T_{i2}$, knowing which we can find the arrival of $T_{i3}$ and so on. It should be clear to the reader that the above adjustment allows all sub-tasks belonging to a task to inherit its period.

What the above adjustment has afforded us is, the ability to treat each of the components independently, provided we are able to find the worst-case completion times $W_{ik}$ ($\forall i, k$). Observe that we have all the information about sub-tasks $T_{i1}$, $1 \leq i \leq n$, running on the first component, $R_1$ (that is, we have their arrival times, periods and execution times). Now the problem we wish to solve is finding the worst-case completion times of these tasks. Once we find these worst-case completion times we have all the information about sub-tasks $T_{i2}$, $1 \leq i \leq n$, running on the second component, $R_2$ and so on. The problem can be formally posed as:

Problem 4. Given a task-set $T$ of $n$ tasks executing on a single component, find the worst-case completion times of all tasks in the task-set.

Now that we have a mechanism to test whether a given task-set is schedulable, we have answered the question of whether there exists a scaling factor as defined by the two problems, Problem 1 and Problem 2. Clearly, if the tasks are so stringent that any increase in the execution times of the sub-tasks cannot be tolerated, then the scaling factors $sfc$ (as defined in Problem 1) and $sft$ (as defined in Problem 2) will both be equal to 1.0.

The end-to-end schedulability problem has been reduced to $m$ single component worst-case completion time computation problems and not $m$ single component schedulability problems. Therefore, we cannot talk about extending a single component’s schedulability, unless we derive the sub-task deadlines. A major research issue in end-to-end scheduling has been the derivation of sub-task deadlines. Given an end-to-end task’s deadline the problem of
arrivals), we can derive an alternate phasing $A'$ which has the characteristic that the arrival times monotonically increase with the priority.

The following theorem is the basis for the approach.

**Theorem 1.** Given that the arrival times of tasks in a task set are inverse monotonic with priority, the worst-case response time instance of a task $T_i$ belongs to the interval $[a_i, a_i + LCM(T_1, ..., T_i)]$.

**Proof.** For task $T_i$, the only tasks that it would have to compete with, are the higher priority tasks $T_1, T_2, ..., T_j$. We are therefore interested in finding that point in time at which, the phasing of task $T_i$ (given by $a_i + x_i \times p_i$, for the $x_i$-th instance) with respect to other higher priority tasks is same as that at time $a_i$. Further, this point must be such that the state of the scheduler must be same as it was at $a_i$.

The relative phasing of task $T_i$ with respect to the task $T_j$ can be captured as: Task $T_j$ comes $a_j - a_i$ units of time after task $T_i$. Assuming the existence of a point where this phasing repeats, and further that there are $x_i$ and $x_j$ instances respectively of $T_j$ and $T_i$ before this point, we have the following condition:

$$(a_i + x_i \times p_i) - (a_j + x_j \times p_j) = a_i - a_j = x_i \times p_j,$$

We can derive similar conditions for task $T_i$ other tasks. The resultant condition is:

$$x_i \times p_i = x_2 \times p_2 = ... = x_j \times p_j = L,$$

where $a_i + L$ is the desired point. Clearly the LCM of $p_j$ is the solution for the above equation if we assume integral values of $p_j$.

Next, we have to show that the state of the scheduler with respect to the task $T_j$ is the same at both points $a_i$ and $a_i + L$. We use the method of mathematical induction to show this.

        $d'_i = a_i + y \times p_i$;
    endif
enddo
return $A'$;
End{Algorithm}.

We take an example (refer to Fig. 2) to demonstrate the operation of the above algorithm. Consider a task-set with four tasks ($T_1, T_2, T_3, T_4$), with the following values for arrival times and periodicities:

$T_1: a_1 = 5, a_2 = 3, a_3 = 4, a_4 = 0, P_1 = 10, P_2 = 10, P_3 = 16, P_4 = 12$.

The first task’s arrival time remains unchanged, however since the task $T_2$’s arrival is before $T_1$’s, its new arrival time, $d_2$, is computed to be $a_2 + p_2$ which is 13. Now task $T_3$’s arrival time $a_3 = 4$ is less than $d'_2 = 13$, therefore its new arrival time $a_3$‘s is $a_3 + p_3$ which is 20. Task $T_4$ arrives at $a_4 = 0$ which is less than $d'_3 = 20$, therefore its new arrival time $d'_4$ is $a_4 + 2 \times p_4$ which is 24. Now the new arrival times of the tasks in the task set are ($d'_1 = 5, d'_2 = 13, d'_3 = 20, d'_4 = 24$).

Before we discuss the mechanism in detail, it is important to ascertain the relationship between the original arrival pleasing and the modified arrival phasing. Since the modified arrival pattern guarantees the repetition of the task-set behavior, in order to find the worst-case response time of any task, we only have to look for its instances between its original arrival time and the point at which the new phasing repeats itself. The algorithm for the complete mechanism follows:

Algorithm 2

Begin{Algorithm}
Input: $A = \{a_1, a_2, \ldots, a_n\}$, and $p_1, p_2, \ldots, p_n$
Find the modified arrival times, $A'$, for tasks by invoking the procedure Arb_to_Incr;
repeat for each task $T_i$ in turn:
    Find the completion times of all task instances of $T_i$ occurring in the interval $a_i$, and $d_i + \text{LCM}(T_j, j \leq i)$;
    Find the maximum and report it as the worst-case completion time of the task $T_i$;
    Compare the worst-case completion time against the deadline to see if $T_i$ meets its deadline;
End{Algorithm}.

We now consider an example (Table 1) task-set to demonstrate the need for accommodating task arrivals as opposed to adapting the critical instant argument. In Table 1, the last two columns give respectively the worst-case response times of the tasks using the critical instant assumption ($W^c$) and our approach ($W^*$). It is clear that the critical instant
In the following, we give an algorithm to find the optimal scaling factor when an arbitrary (RMS and DMS being two instances) fixed priority assignment is used. Before the details of the mechanism are presented we would like to intuitively motivate the idea behind it. We consider the case of scaling all tasks (as opposed to a sub-set) to present the motivation. One approach would be to consider a successive approximation technique as taken by [10]. Incremental factors are used to scale tasks and perform a schedulability analysis to confirm if the increment is acceptable. Clearly, such a technique would be expensive.

An alternative approach would be to incorporate the scaling factor computation into the schedulability test. This is the approach we have taken. The schedulability test we use is the one proposed by Lehoczky in [15]. The idea behind Lehoczky's schedulability test is to ascertain the schedulability of each task in turn starting from the highest priority task. The schedulability of each task involves considering all tasks that are of higher priority than itself. Therefore, the schedulability test of a task \( T_i \) can be interpreted as follows: To ascertain whether task \( T_i \) will meet its deadline while continuing to honor the scaled (scaled by \( s_f \)) requirements of all higher priority tasks. In other words, \( s_f \) is the factor with which the execution times of all tasks with priority greater than \( T_i \) and including \( T_i \) can be scaled without \( T_i \) missing its deadline even after accommodating all the scaled higher priority tasks. The required scaling is then the minimum of all computed scaling factors \( s_f \). A more detailed treatment of the solution follows.

In the discussion above, we assumed that \( T = S \) in order to simplify the explanation of the solution. In this context we gave a definition of \( s_f \) that needs a slight refinement to adapt to the case that the set \( S \) is higher priority task will not wait for the processor while a lower priority task is using it. In other words, it ensures that in every \( p_j \) (\( j < i \)) time units the task corresponding task \( T_j \) would get \( e_j \) units of the processor's time. It is possible for example that a higher priority task \( T_j \) gets its last unit of required execution time between \( d_j \) and \( p_j \) (note \( d_j \leq p_j ; 1 \leq j \leq n \)), thus meeting its demand but not its deadline.

On the same lines our approach to finding the scaling factor attempts to find the scaling factor for each task in turn starting from the highest priority task. The scaling factor (\( s_f' \)) obtained with respect to a task \( T_i \) therefore guarantees that the task \( T_i \) would meet its deadline continuing to honor the scaled (scaled by \( s_f' \)) requirements of all higher priority tasks. In other words, \( s_f' \) is the factor with which the execution times of all tasks with priority greater than \( T_i \) and including \( T_i \) can be scaled without \( T_i \) missing its deadline even after accommodating all the scaled higher priority tasks. The required scaling is then the minimum of all computed scaling factors \( s_f' \). A more detailed treatment of the solution follows.

In the discussion above, we assumed that \( T = S \) in order to simplify the explanation of the solution. In this context we gave a definition of \( s_f' \) that needs a slight refinement to adapt to the case that the set \( S \) is
Step 1: for 
\( (i = h; i \leq n; i + +) \) do

Step 1.1: Compute first approximation for the completion time of task \( T_i \)'s first job:

\[
\text{compl}_0 = \sum_{j=1}^{i} e_j
\]

Step 1.2: Calculate the next approximation for completion time:

\[
\text{compl}_{i+1} = e_i + \sum_{j=1}^{i-1} \left[ \frac{\text{compl}_j}{p_j} \right] e_j
\]

Step 1.3: if \( (\text{compl}_{i+1} > d_i) \)

then The job missed its deadline: Exit(-1);

Step 1.4: if \( (\text{compl}_{i+1} = \text{compl}_i) \)

then we have not arrived at the completion time of the task, so, goto Step 1.2;

Step 1.5: The completion time for the job is \( \text{compl}_i \);

Step 1.6: Fit higher priority task instances that would arrive between the points \( \text{compl}_i \) and \( d_i \). The scheduling points are \( U_{2L}, U_{3L}, \ldots, U_{kL} \), where, \( U_m = U_m - U_{mL} \), denotes the \( m \)-th used time block (refer to Fig. 3).

Further, we identify each used block as a sequence of marked and unmarked sub-blocks where a sub-block of block \( U_m \) is marked (referred to as \( U'_m \), if it is the \( j \)-th marked sub-block of \( U_m \)) if it belongs to the sub-set \( S \) and if its priority is greater than that of task \( T_i \). Unmarked otherwise.

Step 1.7: Compute the maximum possible scaling factor \( sf^i \):

\[
sf^i = \max_{1 \leq m \leq k-1} \frac{\left( \sum_{j=1}^{i} \left( \sum_{j=1}^{i} U'_j \right) + (U_{j+1,L} - U_{j,R}) \right)}{\left( \sum_{j=1}^{i} \sum_{j=1}^{i} U_j \right)}
\]

Enddo

Step 2: \( sf = \text{Minimum} (sf^i) \forall i \)

Step 3: \( sf \) is the required optimal factor.

End Algorithm.

7. Scaling in a single component system: With arrivals

The following section describes a mechanism for finding the scaling factor that incorporates the arrivals of tasks. In order to simplify the presentation we assume that the scaling factor we desire is a common scaling factor for all tasks in the task-set. The case of general scaling (sub-set scaling) can be easily derived on the same lines. As we did when we dealt with the problem of schedulability using arbitrary task arrivals in Section 5, we assume that the arrival times of tasks are in increasing order of their priorities. The important difference between the treatment here and in the previous section, comes from the fact that when we are finding the scaling factor with respect to a particular task \( T_i \), we no
(U_{1,L} - U_{2,L})/(U_{2} + U_{1}), it is possible that the resultant factor does not scale U_{1} to occupy the whole of the idle time between (U_{1,R}, U_{2,L}), resulting in U_{2} being stretched beyond U_{3,L} and consequently the completion time being stretched beyond U_{3,L} (we call this the unfavorable event for this choice of scaling factor NFE2). Note that this possibility has come up because the task T_i is not ready to use the idle time between (U_{1,R}, U_{2,L}). On the contrary, in the event that this factor causes U_{1} to be scaled beyond the point U_{2,L} (we call this the favorable event for this choice of scaling factor, FE2) then clearly the completion time of task T_i will be within U_{3,L} (in fact it will be exactly U_{3,L}).

We note that there are two possibilities (or events) in favor of each of the above choices and two that are not in favor. However, we will show that the true answer lies in finding the minimum of these two possible factors. That is, picking the minimum of these two factors as the solution leads us to realize that the unfavorable possibility is actually not possible. An explanation follows.

We have two possibilities to consider:

- \( f' < f \): The favorable event (FE1) corresponding to this choice of the factor is valid in giving us the desired result. However, we have to show that unfavorable event, NFE1 will not occur. We show this by contradiction: Let us say U_{1} does not get scaled beyond the point U_{2,L} (i.e., the event NFE1 does occur). Since, \( f < f' \), U_{2} does not go beyond U_{3,L} when scaled by f'. However, the very definition of NFE2 says that f stretches U_{2} beyond U_{3,L} when scaled by f'. Hence the result.

- \( f > f' \): The favorable event (FE2) corresponding to this choice of the factor is valid in giving us the desired result. However, we have to show that unfavorable event, NFE2 will not occur. We show this by contradiction: Let us say U_{1} does not get scaled beyond the point U_{2,L} when scaled by f' (i.e., the event NFE2 does occur). Since, \( f > f' \), U_{2} does not go beyond U_{3,L} when scaled by f'. Hence the result.

Observe that the favorable events in both choices of scaling factors achieve the following: The completion time of the task T_i is stretched to the point U_{3,L}. We now extend this to the case that the number of blocks of execution prior to the arrival of the first instance task T_i is more than one. In fact, we wish to extend this argument to the case that there are \( q - 1 \) blocks of execution before the arrival of the first instance of T_i. The generalization is straightforward. If there is more than one block of execution then the scenario would be as in Fig. 4. The scaling factor associated with stretching the completion time of the first instance of task T_i to consume the first idle interval beyond its completion would be given by:

\[
F_q = \text{Min} \left\{ \frac{U_{q+1,L} - U_{1,L}}{\sum_{r=1}^{q} U_r}, \frac{U_{q+1,L} - U_{2,L}}{\sum_{r=2}^{q} U_r}, \ldots, \frac{U_{q+1,L} - U_{q,L}}{U_r} \right\}.
\]
where $q$ is the index of the block that contains the arrival of the first instance of $T_i$. We represent this factor by $F_q$ to signify that this is the factor with which all tasks $T_j$ ($j = i$) must be scaled to fill the first idle interval after the completion (known to overlap with the block $U_q$) of this instance of task $T_i$. The subscript $q$ here is only to identify the block which overlaps with the completion of this instance of $T_i$. The representation will become clear when we proceed to the next stage of derivation, i.e., the scaling factor for an arbitrary instance of $T_i$ (not just the first that is).

Now consider the point corresponding to the deadline of this instance of $T_i$, $a_i + d_i$. Our aim is to try to extend the completion of this instance at most till this point. Clearly, if this point overlaps with a used block (call it $U_{k+1,L}$), then we cannot possibly extend $T_i$'s completion beyond the start of this interval. This is obvious from the fact that the overlapped block in question contains executions of higher priority tasks that cannot be preempted by $T_i$. On the other hand, if the point in question does not overlap with any used block then we can consider filling only part of the idle interval that contains this point, viz., the idle interval between the right end of the used-block preceding the deadline point and the deadline point itself. In this second case, we set $U_{k+1,L} = a_i + d_i = U_{k+1,R}$, i.e., we create a zero sized used block that overlaps with the deadline. Here $k$ is the index of the used-block that precedes the deadline.

Therefore, if we assume that there are $k - q$ such idle intervals beyond $U_q$ and before the deadline of this instance at $d_i$ then we have to find $k - q$ such scaling factors $F_m$ (that is $q \leq m \leq k$). Now, the general formula for $F_m$ is given by:

$$F_m = \min \left( \frac{U_{m+1,L} - U_{1,L}}{\sum_{r=1}^{m} U_r}, \frac{U_{m+1,L} - U_{2,L}}{\sum_{r=2}^{m} U_r}, \ldots, \frac{U_{m+1,L} - U_{m,L}}{\sum_{r=m}^{m} U_r} \right).$$

The scaling factor for the first-instance of $T_i$ is the maximum among all computed factors for accommodating the idle intervals beyond the instance's completion and before its deadline. Therefore, the required factor is:

$$sf = \max_{q \leq m \leq k} F_m.$$

We now have to generalize the above formula for any arbitrary instance of $T_i$ (say the $l$-th). Clearly there are $x_i$ (refer to Section 5) instances of $T_i$ that have to be considered. Therefore, $l$ ranges from 1 to $x_i$. If we find the scaling factors $sf^{il}$ for each of the $x_i$ instances of $T_i$, then we can obtain the scaling factor $sf^i$ as the minimum among all these. This is clear from the fact that picking a factor larger than...
the minimum results in at least one of the instances missing its deadline. So, we have:

$$sf^i = \min_{1 \leq i} sf^{ii}.$$  

In the general case, that is, when we wish to find the scaling factor for an arbitrary instance $i$ we define the following notation (refer to Fig. 6):

- $u$: $U_0$ is the used-block that contains the deadline of the $(l - 1)$-th instance of $T_i$. If, however, $U_0$ is a zero-sized block then $u$ is the index of the next block following the deadline of the $(l - 1)$-th instance at $a_i + (l - 1)p_i + d_i$. As a special case, for the first instance $u = 1$.
- $q$: Is the block that overlaps with the arrival of the $l$-th instance of task $T_i$. This is also the block that contains the completion of the $l$-th instance.
- $k$: $U_{k+1}$ is the block that contains the deadline of the $l$-th instance at $a_i + (l - 1)p_i + d_i$. Note that, if the deadline does not overlap with a used block then we create a zero-sized used-block at $a_i + (l - 1)p_i + d_i$. $k$ is then given by the used-block that precedes this newly created zero-sized block.

The formula for the scaling factor of an arbitrary instance (say $i$) of $T_i$ is now given by:

$$sf^{ii} = \max_{q \leq m \leq k} F_m,$$

where $F_m$ is given by:

$$F_m = \min \left( \frac{U_{m+1} - U_{u,q}}{U_i}, \frac{U_{m+1} - U_{v+1,m}}{U_i}, \ldots, \frac{U_{m+1} - U_{q,m}}{U_i} \right).$$

We now have the scaling factor ($sf^i$) with respect to a task $T_i$. In order to find the final common scaling factor $sf$ we follow the same lines as in Section 5. Accordingly, the required scaling factor $sf$ is given by:

$$sf = \min_{1 \leq i \leq n} sf^i.$$  

The interested reader can find examples demonstrating the solution presented here in [2].

8. Conclusions

To summarize the contributions of the paper:

- We have identified many issues of concern that researchers and practitioners face during the design, development and maintenance of a complex real-time system.
- We have shown that the questions posed by these issues can be formulated from two viewpoints: (1) component changes, and (2) task changes.
- We reduced the above two problems to two fundamental problems viz., schedulability of a task-set (on a single component) with arrival times, and its scalability.
- We have presented optimal solutions to the two problems.

Our solution to the problem of end-to-end schedulability is an important result in that it addresses the distributed aspect of real-time systems. Further, the solution to the schedulability problem in the context of tasks with arbitrary arrivals is an important contribution to the field of static cyclic scheduling [13]. Currently, we are pursuing other applications of the results presented in this paper.

We have found that the scalability result has an immediate application to the problem of admission control in networks with real-time traffic. The problem of admission control is equivalent to asking the question: Having admitted (guaranteed) a set of messages ($n - 1$ of them), is it possible to accommodate
a new message without violating the guarantees of the n - 1 prior messages? Clearly, a simple solution would be to perform a schedulability of all n messages. However, this is an expensive solution in the context of networks. An alternative is to use a heuristic approach to assess the room to accommodate a new message into the network. The heuristic we propose to use is based on the scaling factor of the n - 1 messages already in the network. This measure is then compared against the requirement of the new message to decide whether it can be admitted.

Also research efforts are underway to handle the important research issue of deadline division among sub-tasks of a task. We are attempting to use the scaling factor metric as a heuristic in this process. Finally, we are attempting to optimize the scaling factor computation for special cases (schedulers) of task priority assignments (e.g., RMS, DMS).

Abstract

This paper reports our continuing efforts and initial results with the problem of admission control in real-time networks. This problem was first addressed by the Tenet group, and, their approach was based on the assumption that the link level scheduling was EDD (Earliest Due Date) based. Our work departs from this assumption by addressing the problem in the context of any arbitrary dynamic/fixed priority link level scheduling. Our approach is based on extending a result we have derived in a different context, viz., Task Scalability. It involves assessing the current capacity of a link in terms of its ability to accommodate (scale to) new channels. This assessment (called the admittance measure) is then heuristically compared against the traffic requirements of the newly requested channel to decide its admissibility. A simulation study was performed to study the effectiveness of our approach in improving both utilization of the link and admissibility of channels. Further, we demonstrate the relevance of our heuristic by observing that it reduces to the Tenet schedulability test, for the case of EDD.

1 Background and Introduction

Admission control is the mechanism by which multiple real-time connections can simultaneously share the resources of a packet switching network without resulting in congestion. The connections require guaranteed quality of service (QoS) that is initially (at connection set up) agreed upon. Admission control comes into play when a new real-time connection is being requested. A real-time connection request is accompanied with a QoS list that describes its requirements. Popular QoS requirements in the literature of distributed real-time systems are - throughput, latency (or deadline), packet loss tolerance [2, 4, 6, 7] etc.

*AThis work is partly funded by a grant from NASA (NAG-1-1114)

A popular model used to characterize a real-time connection is a real-time (RT) channel [10]. An RT channel i is characterized by a source and destination (traversing multiple links) and such parameters as, packet inter-generation time (period: gi), packet size (message size: mi) and end-to-end deadline (di). Derivation of the route associated with the connection involves considering both static (network topology) and dynamic (already existing channels) information. In this paper, we assume that the route is given (we are currently investigation the routing problem also). The mechanism used to determine the admissibility of a real-time channel involves verifying at each intermediate link (along the route) in turn, whether the RT channel’s QoS requirements can be guaranteed. If a channel’s requirements can be met at each of the intermediate links then we can accept the channel. If however, the channel’s requirements cannot be met at any of the intermediate link then we can reject the channel. In fact the first such link that deems the channel inadmissible is sufficient to confirm that the channel would not be admissible. Of all the QoS metrics, the latency/deadline metric bears the most relevance to real-time systems. We therefore restrict ourselves to this metric.

In order to test whether a channel’s requirements will be met at an intermediate link we have to know its deadline and its period at that link. Finding the period is straightforward according to the phase adjustment mechanism[9]. Phase adjustment is a mechanism which allows us to extend the end-to-end period (given by the inter-packet generation time) directly to the individual links. Therefore, For a given RT channel its frequency of arrival at an intermediate link is the same as its frequency of occurrence at the source. Deadline derivation, unlike period derivation is a tougher issue. Since the service time of the channel on each of the links is the same, one way to derive the deadlines would be to divide the slack (given by the difference between the end-to-end deadline and the total transmission time of the message) of the RT channel equally among the intermediate links.
However, if one wishes, one can use a more sophisticated heuristic [1, 8] to derive these deadlines. We are presently also investigating other heuristics. Now, the problem of finding the admissibility of an RT channel is equivalent to solving the admissibility at each of the intermediate links [3]. Therefore, from here onwards when we refer to the admissibility of an RT channel we mean its admissibility at an intermediate link. The question of admissibility at a link can be described by the following test:

- **Admissibility Test:** Does the addition of the new channel to the already established channels using this link cause, either the new channel or one of the already established channels to miss their deadline?

Different approaches to the admission control problem (in real-time systems) will differ in the way the above question is answered. Therefore, a study in admission control reduces to the study of this test. Any answer to this question must consider: (i) The scheduling mechanism used at the link, and (ii) Is preemption allowed. The Tenet approach assumes the local scheduling mechanism for messages to be based on the Earliest Due Date (EDD). While a dynamic scheduling mechanism such as EDD gives good performance, its both costly and also results in more preemption. The problem of schedulability of messages is analogous to the problem of schedulability of real-time tasks (in which context EDD was first derived). However, unlike processors where saving the state (and restoring it on being re-enabled) of a preempted process is simple, the same does not hold in the context of messages. To the extent possible therefore, any approach to message scheduling must minimize preemption.

Having said that the above schedulability test is analogous to task schedulability we make the following observations regarding task schedulability:

- Schedulability analysis of a task-set is expensive (time-wise). The only exception being EDD, which has a simple computation that involves checking if the resultant (on addition of the new channel) utilization is less than or equal to 100%.

- For static fixed priority schedulers [5], analyzing the schedulability of a task-set involves verifying for each task in the order of priority whether it meets its deadline.

- The rate monotonic scheduler (RMS) (a static fixed priority scheduler) has a simple schedulability test. It involves checking if the resultant utilization is less than or equal to $n(2^{1/n} - 1)$ (where $n$ is the number of tasks). This condition is sufficient but not necessary for schedulability when deadlines are allowed to be less than or equal to task periods.

The cost involved in doing a precise schedulability test as described by Lehoczky in [5] is unacceptable in the case of message scheduling. This is primarily due to the fact that such a test has to be performed in real-time while the channel is being established. Therefore any question of admissibility has to be answered in a reasonably short time.

## 2 Basic Approach

We discussed how channel admissibility is analogous to task schedulability and also the difficulty in using approaches to task schedulability directly in the context of channels. In this section we present our approach to channel admissibility that is based on a problem derived in a different context [9, 8] - Task Scalability. The task scalability problem can be defined as follows:

**Task Scalability Problem:** Given a set of $n$ tasks. Find the maximum common scaling factor by which the execution times of all the tasks in the set can be scaled, without affecting their schedulability.

Extending this problem to channels and using $n-1$ channels instead of $n$ it reduces to:

**Channel Admissibility:** Given a set of $n-1$ channels. Find the maximum common scaling factor, $s_{f_{n-1}}$, by which the service times of all the channels in the set can be scaled, without affecting their schedulability.

The factor $s_{f_{n-1}}$ as defined above is a measure of the room in the already established channels for accommodating new traffic. In our approach to admissibility, we use this metric in a heuristic comparison against the requirements of the new channel whose admissibility we are attempting to ascertain. The heuristic comparison we use is:

$$\frac{m_n}{g_n} \leq \frac{s_{f_{n-1}} - 1}{s_{f_{n-1}}}$$

where, $\frac{m_n}{g_n}$ is the utilization (traffic) requirement of the new channel. The intuition behind the above heuristic will become obvious in the next section. An important observation to be made in the use of the above heuristic for admissibility is the fact that the scaling factor computation does not occur at the time of channel request. It can be computed immediately after accepting the previous channel. This observation is crucial in justifying the cost involved in the scaling factor computation.
3 Dynamic Scheduling of RT Channels

In [9] we showed that the common scaling factor in the case of EDF (assuming periods are equal to deadlines) is given by the reciprocal of the total utilization of the RT channels.

\[ s_{f_{n-1}} = \frac{1}{\sum_{i=1}^{n-1} \frac{m_i}{g_i}} = \frac{1}{U_{n-1}} \]

The term \( s_{f_{n-1}} \), in the heuristic described in the previous section, can be viewed as the percentage improvement possible in the utilization of the existing channels. The expression can be simplified into the form, \( 1 - \frac{1}{s_{f_{n-1}}} \). It can therefore be seen, how this heuristic turns out to be equivalent to the deterministic test of Tenet (in the context of EDD that is).

Table 1, shows a comparison of our approach (using the scaling factor) and Tenet’s approach when the scheduling mechanism chosen at a link is assumed to be the EDD.

<table>
<thead>
<tr>
<th>Approach</th>
<th>Computation</th>
<th>Test</th>
</tr>
</thead>
<tbody>
<tr>
<td>Tenet</td>
<td>( U_n \leftarrow U_{n-1} + \frac{m_n}{g_n} )</td>
<td>( U_n \leq 1 )</td>
</tr>
<tr>
<td>Scaling</td>
<td>( s_{f_{n-1}} ) (precomputed)</td>
<td>( \frac{m_n}{g_n} \leq 1 - \frac{1}{s_{f_{n-1}}} )</td>
</tr>
</tbody>
</table>

Table 1: Admission Control Test

Clearly, since \( s_{f_{n-1}} = \frac{1}{U_{n-1}} \), the test in column 3 for the Scaling approach reduces to \( \frac{m_n}{g_n} \leq 1 - U_{n-1} \). Which in turn can be rewritten as \( \frac{m_n}{g_n} + U_{n-1} \leq 1 \). Which is exactly, the admissibility test of the Tenet approach. This confirms that, in the context of EDD our approach reduces to the Tenet approach. The next section extends our approach to general fixed priority link level scheduling.

4 Fixed Priority Scheduling of RT Channels

We have shown in [9] that there is no straightforward way to compute the scaling factor of a set of tasks (read as RT channels in the present context) scheduled by a general fixed priority scheduling mechanism. However, in the particular case of RMS (again, assuming deadlines are equal to periods), we can find a non-optimal scaling factor that is given by:

\[ s_{f_{n-1}} = \frac{(n-1)(2^{1/(n-1)} - 1)}{U_{n-1}} \] (1)

This factor is not optimal in the sense that it is possible to improve it further. In other words, failing to pass the heuristic test (using the above factor) does not necessarily imply that the new channel will interfere with the schedulability of the already existing channels. This implies that, using the heuristic it is possible that a new channel request is rejected even though it could have been accommodated.

An alternative to the above computation is to use a more precise computation, one which would help us obtain an optimal scaling factor. We have shown in [9], how such a computation works. An important consideration in deriving this result is that deadlines are assumed to be less than or equal to periods as opposed to making a restricted assumption that they are equal. This alternative is appealing in its ability to reduce the number of rejections (as described in the previous paragraph). However, it does not necessarily guarantee 100% admissibility. 100% admissibility is said to be achieved if the test never rejects a new channel that would have not interfered with already accepted channels. The failure of this alternative to ensure 100% admissibility is due to the fact that though the scaling factor computation is precise, the comparison in which it is used is a heuristic. Note also, if the benefit (reducing the number of rejections) obtained by using the optimal scaling factor is not large enough (compared to using the non-optimal computation), we cannot justify its use. Since, the basis of the test is a heuristic, the only way one can confirm the benefits is to perform a simulation study.

5 Results

The following preliminary observations were made from the data collected from a simulation performed to assess the performance of the heuristic. The two cases that were compared are, the heuristic \( \mathcal{R} \) using the non-optimal computation of the scaling factor (Equation 1) and the heuristic \( \mathcal{S} \) using the optimal computation of the scaling factor reported in [9].

- For low utilizations we observe that both the heuristics have a similar admissibility. Given that the heuristic \( \mathcal{R} \) is less expensive (computation time-wise) than \( \mathcal{S} \), under conditions of low utilizations one can choose the heuristic \( \mathcal{R} \).

- For a given value of \( n \) (number of channels) and \( \kappa \) (parameter dictating the tightness of deadlines) we observe that the admissibility of heuristic \( \mathcal{R} \) falls abruptly beyond a point given by the utilization bound. For example, when \( n = 8 \) and \( \kappa = 60 \), the heuristic \( \mathcal{R} \) begins to reject channels when the total utilization crosses beyond 72%.

- The performance of \( \mathcal{S} \) degrades gracefully beyond the utilization bound. For example, when \( n = 8 \)

\[ \text{The plots from the simulation study are not included here due to space restrictions} \]
and $\kappa = 80$ the heuristic $S$ continues to admit channels up to a total utilization of 92%. The probability of acceptance decreases gradually (and steadily) however. This implies that the heuristic has a better ability to adapt to temporary overloads (increased demand from one of the channels) in the network traffic.

- As the number of channels increases, the performance degradation beyond the utilization bound is slower in the case of heuristic $S$. This goes on to support the ability of the heuristic to adapt to temporary overloads (increase in the number of channels). The two sources of overload have been successfully handled by the heuristic $S$.

- As the number of channels increases the success of the heuristic $S$ improves compared to the heuristic $R$.

- $S$ has better performance with respect to rejecting inadmissible channels compared to $R$. Thus proving the sensitivity of the heuristic and its ability to avoid incorrect admissions.

- In conclusion we can say that for low utilizations both heuristics have similar performance (however one should prefer the heuristic $R$ due it computational ease) but, at high utilizations $S$ far outperforms $R$. Further, we can justify the cost of computation involved in $S$ by noting that the computation can be done before the actual channel request is made.

6 Conclusions and Future Work

A significant contribution of the work reported in this paper is a heuristic based admission control mechanism that can be applied for any arbitrary scheduling mechanism. The schedulers considered spanned both dynamic (EDD) and static (RMS) schedulers. Further, in the static scheduling scenario, we can easily extend the admission control mechanism to any fixed priority assignment. The need for being able to accommodate any arbitrary priority assignment arises from the fact that channels derive their importance (and so their priority) from the inherent purpose they serve relative to other channels and not by their demands (as characterized by the parameter deadline in EDD and the parameter periodicity in RMS).

In the treatment of the admission control problem above, we have assumed that the route that a channel traverses is given to us. We are currently investigating mechanisms by which such a route can be built. The mechanisms can exploit the scaling factor problem described before. As described already the scaling factor for a link's traffic (corresponding to the factor with which the requirements of channels already passing through the link can be scaled) gives a measure of the available room in the link with regards to accommodating new channels. We can use this measure in building the route to be traversed from a given source to destination. We are considering two alternatives here: (i) Source routing, and (ii) Hop-by-Hop Routing.

An important research issue that was alluded to in section 1 was the derivation of a channel's deadline at intermediate links. We presented one approach to this derivation that simply divides the deadline equally among the links. It is our belief however, that this problem needs further investigation and therefore has been, the subject of our current research.

The heuristic used in comparing the new channel's requirement against the links current load (characterized by the scaling factor) was shown to work well in the context of dynamic schedulers. However, in the context of static schedulers, it is our belief that the heuristic needs further validation.

References

The number and complexity of applications that run in real-time environments have posed demanding requirements on the part of the real-time system designer. It has now become important to accommodate the application complexity at early stages of the design cycle. Further, the stringent demands to guarantee task deadlines (particularly in a hard real-time environment, which is the assumed environment in this thesis) have motivated both practitioners and researchers to look at ways to analyze systems prior to run-time. This thesis reports a new perspective to analyzing real-time systems that in addition to ascertaining the ability of a system to meet task deadlines also qualifies these guarantees. The guarantees are qualified by a measure (called the scaling factor) of the systems ability to continue to provide these guarantees under possible changes to the tasks. This measure is shown to have many applications in the design (task execution time estimation), development (portability and fault tolerance) and maintenance (scalability) of real-time systems. The measure is shown to bear relevance in both uniprocessor and distributed (more generally referred to as end-to-end) real-time systems.
However, the derivation of this measure in end-to-end systems requires that we solve a fundamental (very important, yet unsolved) problem—the end-to-end schedulability problem. The thesis reports a solution to the end-to-end schedulability problem which is based on a solution to another fundamental problem relevant to single-component real-time systems (a uniprocessor system is a special instance of such a system). The problem of interest here is the schedulability of a set of tasks with arbitrary arrival times, that run on a single component. The thesis presents an optimal solution to this problem. One important consequence of this result (besides serving as a basis for the end-to-end schedulability problem) is its applicability to the classical approach to real-time scheduling, viz., static scheduling. The final contribution of the thesis comes as an application of the results to the area of real-time communication. More specifically, we report a heuristic approach to the problem of admission control in real-time traffic networks. The heuristic is based on the scaling factor measure.

Acknowledgements

First and foremost I owe this thesis to the part of me that persisted inspite of the frustrations of pursuing a seemingly never ending goal, that is a PhD thesis. I'd like to thank my advisor Dr. Ravi Mikkamala for believing in my abilities and constantly reminding me of what little was left for me to finish my thesis. Though it was never “little”, I am glad I took his advice. I would like to acknowledge the financial support I received from NASA Langley Research Center for pursuing my thesis. I thank Mr. Wayne H. Bryant, Assistant Division Chief, Flight Electronics Technology Division, NASA LaRC, for approving and funding my thesis proposal under the grant NAG-1-1114.

I would like to thank my committee - Dr. Kurt Maly, Dr. Hussein Abdel-Wahab, Dr. Larry Wilson and Dr. John Stoughton for their support and approval of my work. Both Dr. Maly and Dr. Wahab have tolerantly guided me through the preliminary stages of my PhD. I'd like to acknowledge Dr. Stoughton's valuable comments on the final thesis. Among other faculty, Dr. Stephan Olariu and Dr. Chester Grosch have contributed significantly in making my stay at ODU academically worthwhile. I'd also like to acknowledge the arrival of Sameera (who has since become my wife) into my life in August of 1994 which also overlapped with my finding most of the results reported in this thesis. In a sense, this presents a case against the popular french saying “The first sigh of love is the last sign of wisdom”. I would like to thank all my
colleagues in the Computer Science department for giving me company through the travails of graduate life. In particular I'd like to thank Dharmavani for her prodding me not to quit my PhD. Lastly, I'd like to thank my high school tutor, Mr. Gopalan, to whom I owe dearly for my academic achievements. He built in me a fascination for logical reasoning and thought.

Chapter 1

Introduction

The scope of real-time systems has expanded over the last two decades to encompass a wide array of applications such as industrial process control systems, nuclear power plants, air traffic control systems, aircraft navigation, robot navigation and automobile control. While, in the past these systems were predominantly centralized, most current approaches tend to be distributed in nature. Further, the complexity of these systems (in addition to that added by its distributed nature) has grown rapidly to a point where the dependability (or determinism) of the system as a whole has become an important issue. Real-time systems are primarily categorized into two types, hard real-time systems and soft real-time systems. In hard real-time systems, the missing of task deadlines can lead to severe consequences and hence there is a strict need to meet these deadlines. In contrast, soft real-time systems are characterized by the fact that they can tolerate temporary deadline misses. Soft real-time systems continue to operate even after missing deadlines, and the only consequence being a temporary decline in performance and an increase in response time. For example, a robot operating in a hazardous terrain would be a hard real-time system and a system that periodically generates a weather report can be considered a soft real-time system.
The stringent need to meet deadlines in hard real-time systems implies that there is a need to analyze the system pre-runtime, to ascertain its ability to guarantee performance (that is meeting deadlines). Therefore, this has motivated enormous efforts from practitioners to investigate the system behavior prior to its actual installation. In other words, though the system is said to function in real-time, the guarantees it provides in meeting the timing requirements of the various tasks have to be ascertained a priori. This thesis presents issues and finds solutions that we believe will aid practitioners in guaranteeing system behavior prior to run-time in hard real-time systems. The issues in soft real-time systems overlap significantly with those in conventional systems where the primary performance metrics are throughput and response time (an average measure unlike deadline that is an absolute measure). These systems have been well-studied and the results (pertinent to these systems) are directly applicable to soft real-time systems.

A real-time system can be characterized by two important components: the environment in which the system is operating and the computer system that controls/monitors the environment. The main issues in the design of the first component concern interfacing with the environment [41]. Solutions in this area are primarily dictated by the technology. There are many issues of concern in the design of the second component, the computer system. The computer system involves both the hardware and the software that runs on them. The choice of hardware is dictated primarily by such parameters as cost, availability and the application at hand. The primary issue in software design is not so much the particular choice of language or programming paradigm as it is the mechanism by which the various tasks are scheduled.
1.1 Issues in Real-Time Systems

We observe that only the last issue (mentioned above) can be speculated over because the others are more or less dictated by the environment and the application at hand. This is the reason why we have efforts from numerous researchers [40, 48] on the problem of scheduling in real-time systems. There have been two important fronts of research: On one front there have been efforts [2, 20, 22, 24] to find scheduling mechanisms that could guarantee performance under different assumptions about the system. On a second front, researchers [46, 19, 3] have tried to answer questions posed by schedulability analysis. Both these are inter-related in the sense that schedulability analysis is a mechanism to evaluate the effectiveness of a scheduler. To this end, in the following discussion when we refer to schedulability we implicitly assume that the tasks are being scheduled by an arbitrary scheduler (where appropriate, we give a more detailed description of the scheduler assumed). If a scheduler is built on a strong theoretical basis then its schedulability analysis can be a trivial comparison. For example, a dynamic scheduling mechanism, the earliest deadline first (EDF) scheduler, has the theoretical property that, provided the sum of the utilizations\(^1\) of the tasks in a task-set is less than 1, the EDF scheduler guarantees to meet their deadlines (schedulable). Clearly, in this case the schedulability test is a simple one. There are other cases where the schedulability test is non-trivial [19, 50].

A common assumption that distinguishes one scheduling mechanism (and thus the corresponding schedulability analysis) from another is the oper-

---

\(^1\)The utilization of a periodic task is given by the ratio of its execution time requirement to its periodicity
ational environment of the real-time system. If the environment is completely known a priori, then we can use a static approach to design a scheduler. The schedule can be practically pre-computed (as a list), with the scheduler being a simple mechanism to pick the next task in the list. On the other hand, if the environment is dynamic by nature and no a priori knowledge can be assumed about the environment then the scheduling mechanism must be dynamic, adapting to the changing needs of the system. Clearly, a dynamic scheduler is more expensive (in terms of overhead) to implement compared to a static scheduler.

The use of dynamic approaches are perfectly justified in systems where the various internal (system) and external (environment) tasks characteristics are not known a priori [40]. However, we observed that such systems are far outnumbered by those where the environment is well understood, deterministic (in the sense that the worst possible scenarios can be identified), and with tasks whose timing, resource, communication and other requirements are known a priori [49]. This thesis addresses a host of related problems that concentrate on such static environments.

1.2 Issues Addressed in this Thesis

The problems of interest to us in this study are motivated by the evolutionary nature of real-time system software. As real-time systems continue to grow in size and scope there is a need to build portable standard software that would be guaranteed to operate correctly both in the logical and the temporal sense. By correctness in the logical sense, we are referring to the domain of proving the correctness of a piece of software with regards to generating a
correct output for any given input (The traditional program correctness issues).
The emphasis of research in real-time systems has been not so much to prove logical correctness as it has been to show that the output is produced in a timely manner. Therefore, a logically valid output generated beyond a specified time limit is deemed incorrect. In this thesis, we concentrate primarily on the temporal correctness.

This notion of correctness (temporal that is) of a task in real-time systems has been captured by the concept of schedulability [46] of tasks. A task is primarily characterized by the following parameters: the arrival time, the execution time, the periodicity and the deadline. Schedulability analysis therefore attempts to ascertain whether or not each task will be able to complete its required execution before its deadline for all its instances when scheduled by an assumed scheduler. Tasks being periodic, they occur repeatedly at an interval given by their period. Various such occurrences of tasks are referred to as instances. The basic approach taken in schedulability analysis is to use the information about tasks' arrival times, execution times and periodicities and compute their worst-case completion times assuming that they are scheduled by a given scheduler. The worst-case task completion times so computed are compared against their deadlines to determine if the tasks will be schedulable. Therefore, the worst-case completion time computation is the essence of schedulability analysis.

We are not interested in deriving new schedulability tests but rather in extending the guarantees made by schedulability analysis as a system undergoes changes. The types of changes we are mainly interested in, manifest themselves as changes in execution times of tasks. In Chapter 3 we discuss sources of such
changes pertinent to the design, development and maintenance of real-time systems. More specifically, we are interested in the effects on the guarantees made by schedulability analysis when some or all of the tasks' execution times are scaled (up or down)\textsuperscript{2}. We refer to this problem as scalability of real-time systems. There are two important scenarios in which the factor has relevance: (i) Uniprocessor systems and (ii) end-to-end systems.

The problem of scalability in uniprocessor systems can be informally defined as follows:

Given a task-set $T$, determine the maximum scaling factor with which a subset ($S$) of these task-set's execution times can be scaled without affecting the schedulability of the task-set.

If a task-set is not-schedulable\textsuperscript{3} to start with then scaling a subset of the task will in no way improve the situation and this case is of no interest to us. On the other hand, if a task-set is schedulable to start with, then we are guaranteed the existence of a scaling factor (possibly 1, in the case that the task-set requirements are tight) that does not affect the task-set's schedulability. The first step therefore is to find whether the given task-set is schedulable. In the context of uniprocessor systems, Lehoczky's [19] schedulability test can be used for this purpose. Finding the scaling factor now can be viewed as extending this schedulability test to accommodate for changes in task execution times. There are two possible approaches here: (i) using an approximation

\textsuperscript{2}Scaling down of task execution times can be trivially handled, therefore from here onwards when we refer to scaling we mean scaling up

\textsuperscript{3}That is, at least one of the tasks misses its deadline when scheduled by the assumed scheduler.
technique by making small increments to the scaling factor (starting from 1) and repeatedly performing the schedulability test, or (ii) embedding the scaling factor computation into the schedulability test. We have taken the second approach for performance reasons that will be described in detail in chapter 4.

As opposed to uniprocessor systems where we have a single schedulable resource, end-to-end systems (e.g., a distributed system) have more than one schedulable resource. Therefore an end-to-end system can be characterized by tasks that do not necessarily execute on a single component. Typically, a task would comprise of a sequence of sub-tasks that each execute on a different component (e.g., processors, network) in the system. The requirements of period, deadline and arrival time are specified for the task as a whole with the execution times being specified at the sub-task level. The problem of finding the schedulability (worst-case completion time computation) of a task \( T_i \) in such a scenario can be reduced to solving the schedulability of the \( m \) (number of sub-tasks in task \( T_i \)) sub-tasks in turn, provided we are able to compute the characteristics (period and arrival time) of the sub-tasks \( T_{ik} \) \( 1 \leq i \leq n; 1 \leq k \leq m \). For reasons that will become clear in chapter 3, we cannot use Lehoczky's schedulability test for the sub-tasks running on these individual components.

The scalability problem in the context of end-to-end systems takes two forms depending on whether we view the scaling to occur as a result of a change in one or more of the components or a change to a subset of the sub-tasks. Solving either of these two forms requires that we first find whether the

---

4We use the term component to indicate any schedulable entity in the system.

5The treatment in this study is restricted to sequential tasks, however, it can be extended to more complex tasks.
given task-set (of end-to-end tasks) is schedulable to start with (we call this end-to-end schedulability). Secondly, we have to extend this schedulability test to accommodate component and/or task changes.

We have investigated the applicability of the scalability problem in other areas of real-time systems. Particularly, in the area of real-time communication. The application of interest to us is admission control in real-time (RT) channels [9, 8]. The role of real-time channels in communication is analogous to end-to-end tasks in distributed systems. Admission control poses the question: “Having guaranteed the performance requirements of \( n - 1 \) real-time channels, is it possible to admit a new real-time channel, while continuing to honor the guarantees already made?” The problem of admission control is analogous to: “Given a schedulable task-set of \( n - 1 \) end-to-end tasks, is it possible to accommodate a new task without violating the schedulability of the \( n - 1 \) prior tasks?”

1.3 Summary of Results

The primary contribution of this thesis to the area of real-time systems is in presenting solutions to the following two fundamental problems related to schedulability analysis. The first of these problems involves schedulability analysis of task-sets where tasks have non-zero arbitrary arrival times. The second involves extending schedulability analysis to accommodate scaling up of task execution times. The impact these problems (and their solutions) have on the current state-of-the-art of real-time system research can be summarized as follows:
• Helps real-time system designers in doing a precise analysis of task-sets. Such a precise analysis, as opposed to the pessimistic analysis approach that was popularized by the RMA [6] (Rate Monotonic Approach) group at SEI helps prevent under-utilization of system resources.

• The thesis identifies many important issues in real-time systems that motivate the need for using the arrival time information of tasks in schedulability analysis. Prominently, the issues of data and resource sharing among tasks, precedence constraints between tasks, controlling task jitter can be addressed naturally by the use of task arrival times.

• The use of static schedules was popular in practice in real-time systems till the late 70s. The approach however, suffered from the inability to guarantee task schedulability a priori as opposed to RMA, which was based on the critical instant argument. As a by-product of doing a schedulability analysis of task-sets with arrival times (reported here), we are able to build static schedules whose ability to guarantee task schedulability can be ascertained a priori.

• There is no known schedulability analysis approach in the context of distributed real-time systems (or more generally end-to-end real-time systems). Using the single-component schedulability analysis of tasks with arbitrary arrivals, we are able to perform an end-to-end schedulability analysis.

• The thesis reports the first effort in addressing the issues of scalability and portability in real-time systems.
• The scaling problem is shown to help address issues of concern to designers in the design, development and maintenance real-time systems. In the design phase it allows us in analyzing the task-set by assuming an arbitrary target environment which can be later adapted to a specific target environment. In the development phase it allows us to add new tasks or enhance the existing task’s functionality. In the maintenance phase it helps address the ability of the system to tolerate faults.

• The scalability problem is also solved in the context of distributed systems.

• Lastly, we report a heuristic approach to the problem of admission control in real-time traffic networks. The heuristic used is based on the study of the scaling factor problem.

1.4 Organization of the Thesis

The rest of the chapters of the thesis are organized as follows. Chapter 2 lays down the framework and terminology used through the rest of the paper. We describe the uniprocessor system model and task characteristics of interest to us. The special sense attributed to the arrival time parameter leads to the consideration of dependent and independent task-sets. The end-to-end system model is defined both in a restricted flow-shop sense and also a more generalized sense. Finally, the real-time channel model used in the study of admission control in real-time traffic networks is described.

In Chapter 3, we give a brief discussion on some theoretical background in scheduling that is pertinent to this thesis. In particular we discuss the
work of Lehoczky in the context of schedulability analysis of fixed priority schedulers. The use of the critical instant argument and its consequences in both uniprocessor and end-to-end systems is critiqued. We also discuss the limited work reported in the areas of end-to-end scheduling and admission control.

In Chapter 4, the problems of interest in this thesis are formally stated and their solutions are shown to reduce to solving three fundamental problems that are the subject of the next four chapters. Chapter 5 presents the problem of uniprocessor scalability. A pre-requisite to solving the end-to-end scalability problem is the end-to-end schedulability problem which is the subject of Chapter 6. Chapter 7 considers the end-to-end scalability problem from two different perspectives viz., component change and task change.

The problem of admission control of real-time channels is the subject of Chapter 8. Here, we discuss a simulation study to compare two heuristics to solve the admission control problem.

Finally in Chapter 9, we describe a detailed example that puts the reported results in perspective and also concludes this thesis. The chosen example is derived from the case study of the "Olympus Attitude and Orbital Control System" (AOCS). This case study was performed by Alan Burns and his colleagues at University of York in association with British Aerospace Space Systems Ltd. for ESTEC.
Chapter 2

System Model

In this chapter, we introduce the modeling assumptions and establish the notation and terminology used in the rest of the thesis. We identify three models relevant to the thesis viz., uniprocessor system model, end-to-end system model and real-time channel model.

2.1 Uniprocessor System Model

The uniprocessor system model is characterized by the fact that there is only one allocatable component in the system, viz., the processor. More generally, this model can be referred to as "single component model." The role of the processor is to monitor/control the target environment. For example, if the environment is that of a chemical experiment, then the processor interacts with the environment through sensors and actuators. The sensors serve to convey the current information about the experiment as inputs to the processor. These inputs together with locally (local to the processor) maintained state information capture the state of the experiment. The processor performs predetermined

\[\text{footnote}{1}\text{The term component is used to refer to any independently schedulable resource. Examples include, processors, communication medium, input/output processors, disk storage etc.}\]
operations on these inputs (along with the information) and generates outputs that are then conveyed to the experiment through the actuators. Therefore, the interaction of the processor with the environment in which it operates can be captured by the inputs and outputs.

The operations which process the inputs to compute the outputs are contained in the tasks. In addition, to tasks that operate on the external inputs, we can also have tasks that are triggered solely by internal events or timed events. The operation of the complete system can be captured by specifying the characteristics of its tasks. There is one distinguishing characteristic about tasks that affect the complexity of the system, viz., task dependence. We therefore identify the following two cases separately. The following description applies for both these scenarios:

Here, $n$ independent tasks, $\{T_1, T_2, \ldots, T_n\}$, capture the activity performed on a processor. Each task $T_i$ ($i$ is called the identifier of the task $T_i$) is characterized by the following parameters:

- $e_i$: The execution time requirement of a task. Note that if we look at the model as a “single component model” then this parameter could mean the service time requirement of the task from the component in question.

- $a_i$: The arrival time of the first instance of a task. This parameter is also referred to as the offset of the task. Given a task-set $T$ we can assume that the task that is the earliest to arrive (say $a_{\text{min}}$) does so at time $t = 0$ ($a_{\text{min}} = 0$). Therefore all other task arrival times are relative to this reference.
• \( p_i \): The periodicity of a task. Consistent with the assumptions of researchers in real-time systems, we assume that tasks are of a periodic nature. This parameter implies that a task would be ready for execution every \( p_i \) units of time. We refer to successive occurrences of a task as its instances or jobs. Therefore the \( j^{th} \) instance of task \( T_i \) will be referred to as \( T_i^j \). As opposed to periodic tasks, aperiodic tasks are characterized by the fact that they are not strictly periodic. However, the minimum inter-arrival time between successive occurrences of an aperiodic task is assumed to be known. Note that in case the task is an aperiodic task we treat this parameter \( (p_i) \) to be the minimum inter-arrival time between the task’s successive instances.

• \( d_i \): The deadline of a task. Every instance of a task is required to complete its execution before the task deadline. Therefore, if the first instance of a task \( T_i \) arrives at time \( t = 0 \) then its deadline is at time \( t = d_i \). Subsequently, the \( j^{th} \) instance will arrive at time \( t = a_i + (j - 1) \times p_i \) and will have its deadline at time \( t = a_i + (j - 1) \times p_i + d_i \). Throughout the study, we assume this parameter of a task to be less than or equal to its period. In other words, the completion of a task’s instance can be delayed at most till its next instance arrival. In this study we assume this to be a hard deadline. This assumption can be justified as follows: The problems we are interested in, involve schedulability analysis which is typically done offline and before the actual system is built. If the offline analysis would show that a task’s deadline cannot be met, then the factors that the analysis failed to account for (compared to the real system) would make the task’s chances of meeting its deadline only worse.
Therefore it would seem only logical to assume the deadline to be a hard deadline.

- **$Pr_i$:** The relative priority of the task in the system. We assume that every task has a priority assigned to it. The priority could be dictated either by the scheduler (e.g., the rate monotonic scheduler assigns priorities to tasks based on their periods) or by the inherent importance of the task relative to other tasks in the system. Unless specified otherwise, we assume that the tasks are ordered in the non-increasing order of their priorities. A simple transformation can convert this non-increasing order to a strictly decreasing order. For example consider a task-set, $T$ containing 5 tasks with priorities, $Pr_1 = 9, Pr_2 = 8, Pr_3 = 8, Pr_4 = 4, Pr_5 = 2$. Tasks $T_2$ and $T_3$ have the same priority. Since equal priorities are arbitrarily broken, we can reassign $T_3$'s priority, (say to 6) to be smaller than $T_2$'s (we use task identifiers to break conflicts between tasks). Note that if $Pr_5$ was equal to 7 and the priorities had to be integers then we cannot assign a new priority to $T_3$. In such a case we can reassign new priorities to $T_4$ and $T_5$ in order to make room for $T_3$. In other words, the transformation guarantees that the first task $T_1$ is the highest priority task and the priority of task $T_j$ is greater than $T_i$ if and only if $j < i$.

- **$W_i$:** The worst-case response time. This is also referred to as the worst-case completion time of task $T_i$. This term gives the worst possible time elapsed between an instance of the task $T_i$'s arrival and its corresponding completion. Clearly, if the response time of the $j^{th}$ instance of the task $T_i$ was $W_i^j$ then, $W_i$ is given by the maximum $W_i^j \forall j$. 
The characteristic that distinguishes the two scenarios of independent and dependent tasks arise from assumptions about the arrival time parameter.

### 2.1.1 Systems with Independent Tasks

The arrival time $a_i$ is the arrival of the first instance of a task. Task independence is primarily captured by assuming that the arrival times of tasks do not have any interdependence. Therefore leading to the assumption that the arrival times of all tasks are equal to zero. This assumption has a significant impact on the study of task schedulability. It allows us to use the critical instant argument. The critical instant argument is used in finding the schedulability of the $i$'th task among $n$ tasks scheduled by a fixed priority scheduler. It can be briefly summarized as follows:

A task $T_i$ suffers its worst-case completion time (or response time) when its arrival coincides with the arrival of every other higher priority task $T_j$ ($i < j \leq 1$). Such an arrival is called a critical instant for the task $T_i$. 

It is important to understand that the occurrence of the critical instant for a task $T_i$ is not mandatory, in the sense that given a task-set (of tasks with arbitrary arrivals) a task is not guaranteed to encounter its critical instant. To this end, we assume that the arrival times of tasks are given to be zero, thus forcing the occurrence of the critical instant. Therefore, the critical instant argument is sometimes referred to as the critical instant assumption.
2.1.2 Systems with Dependent Tasks

The case for considering task dependence has been addressed by many researchers in different contexts [49]. Krithi Ramamrithm, in his discussion [41] on the complex nature of real-time environments states that, task interdependence contributes significantly to the complexity. Alan Burns makes similar observations in the context of the case study on the Orbital Control System [5]. Here, we briefly list some situations that impose task dependence. We also identify how these different situations can be addressed by incorporating the offset (arrival time) parameter defined in the previous subsection.

- Data and Resource Sharing: It is important to regulate the accesses of multiple tasks to a shared data item or resource. A costly solution to this problem is to implement a concurrency control mechanism (such as the priority ceiling protocol [33]). As an alternative to using a concurrency control mechanism, we observe that by inhibiting two or more tasks from accessing a resource simultaneously we can regulate their access [45]. Such an inhibition can be achieved by deriving suitable arrival times (offsets) for tasks. For example, if two tasks, $T_i$ and $T_j$, access a common resource (or data item) then with the knowledge about their expected duration of use of this shared resource one can arrive at their relative arrival times. These arrival times can be computed such that the request by $T_j$ always follows the release by $T_i$. In other words, we can impose constraints on the tasks to the effect that their accesses to the shared entity are ordered. This situation can be described as an exclusion constraint that was solved by imposing a precedence order on the tasks.
• Precedence Constraint: If the tasks inherently possess a precedence constraint, then it would directly manifest itself as an offset in each task. For example, if the partial results (outputs) generated by a task $T_i$ are used (as inputs) by a second task $T_j$, then we are forced to impose the condition that the task $T_j$ will be ready to execute only after $T_i$ completes. Therefore, there is an inherent precedence constraint on $T_j$. The conveyance of these partial results can be done either through shared memory or through communication. Thus, inter-task communication can also impose precedence constraints.

• Controlling Task Jitter: The irregularity in the response times (different instances) of a task $T_i$ can hurt the schedulability of tasks that depend upon its output [27]. This entails an output jitter bounded (from above) by the difference of the worst-case response time and the task’s execution time. The output jitter of a given task $T_i$ can be reduced by dividing it into two tasks $T_j$ and $T_k$. $T_j$ performs the bulk of the execution and writes the results to a buffer shared by $T_j$ and $T_k$; $T_k$ is released at an offset from task $T_j$ that is large enough to ensure that the data is always available. This approach can also be used to bound jitter on input [45].

From the above discussions it is clear that, task dependence can be captured by the notion of timing offsets for tasks. Further, given a task-set and the details of inter-task dependencies, we can arrive at individual task arrival times.
2.2 End-to-End System Model

This model differs from the uniprocessor system model (single component model) in that it considers more than one independently allocatable component in the system. A task in such a system can require execution on multiple components. Hence, a task is no longer viewed as an indivisible entity but as a sequence of sub-tasks. We assume that each sub-task of a task is associated with a component. Therefore a task that uses \( r \) components is decomposed into \( r \) sub-tasks, one corresponding to each component. A discussion of reasons and guidelines for task-decomposition can be found in [49].

We assume that the components in the system are ordered. The traditional flow-shop model [4] is based on the assumption that all tasks in the task-set access all resources and that they do so in the same order. A more general view to flow shops would be to relax the requirement about tasks having to access all resources but still maintaining the order constraint. This model will be referred to as the ordered flow shop model. If there are \( m \) components in the system, \( R_1, R_2, \ldots, R_m \), then a task \( T_i \) can be considered to be a sequence of sub-tasks \( T_{i1} \rightarrow T_{i2} \rightarrow \ldots \rightarrow T_{im} \). In the case of traditional flow-shop model, each sub-task \( T_{ik} \) is required to have a non-zero execution time requirement on the component it runs. Ordered flow shop model relaxes this constraint.

A sub-task \( T_{ik} \) of task \( T_i \) is characterized primarily by its execution time requirement on the component \((R_k)\) it runs. In the case of the ordered flow shop model, if a component \( k \) is not used by a task \( T_i \) then the execution time requirement of the task \( T_{ik} \) is assumed to be zero. The parameters of periodicity and deadline are characteristics of a task and not that of the sub-tasks. Since these parameters apply to the task as a whole (from the start
of the first sub-task to the end-of the last sub-task) we refer to these as the end-to-end parameters of the task. The last parameter associated with the task is its priority $P_r$, which may be inherited by its sub-tasks. Alternatively, we can allow individual sub-tasks of a task to be assigned priorities independently. Unless otherwise specified, throughout this study, we assume that sub-tasks of a task inherit its priority.

2.3 Real-Time Channel Model

The two models described above are computational models. The real-time (RT) channel model however is a communication model that abstracts the communication activity in real-time packet switched networks [42, 38]. A real-time channel is uni-directional\(^2\). An entity (say a process) wishing to communicate with another entity on a remote machine does so by establishing a real-time channel that has certain characteristic timing and buffer space requirements.

A real-time (RT) channel timing requirement can be defined by the following parameters:

- The minimum message inter-generation time
- A *maximum* message size
- An end-to-end deadline for the RT channel

It is reasonable to assume prior knowledge of these parameters for many applications such as real-time timing control and monitoring, interac-

\(^2\)A bi-directional R-T channel can be created by combining two uni-directional RT-channels [54]
tive voice/video transmission and many other multimedia applications. In applications where these parameters are less predictable, estimates can be used. Note that any guarantees that the underlying communication subsystem provides to the application is sensitive to the ability of the application to correctly specify its requirements. In this thesis, we are not interested in how such a correct specification is achieved, but given such a specification, how does the underlying system guarantee its being met.

Formally, an RT channel can be defined as follows [53]:

**Definition 2.3.1** A real-time channel $C_i$ described by a tuple $(g, m, d)$ is a connection between two nodes and require that every message at the source be delivered to the destination in duration of time no longer than $d$, under the conditions that the message inter-generation time is $g$, and the message size is $m$.

This definition of an RT channel helps in network management and also provides a convenient means of charging users for their connection requests. For example, a user will pay lower connection fee for a voice channel than a video channel since the former uses less bandwidth. A connection that demands a low end-to-end delay (or deadline) is likely to cost more than one that tolerates a higher end-to-end delay (or deadline).

### 2.4 Glossary of Notation

The following table summarizes the notation used throughout the thesis.
Table 2.1: Glossary of Notation

<table>
<thead>
<tr>
<th>Notation</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>$t$</td>
<td>Time</td>
</tr>
<tr>
<td>$T$</td>
<td>A task-set</td>
</tr>
<tr>
<td>$T_i$</td>
<td>The $i^{th}$ task in a task-set $T$</td>
</tr>

Chapter 3

Motivation and Relevant Background

We are interested in extending the current schedulability analysis to accommodate changes in task execution time. It is only befitting to spend some time in describing the principles and assumptions that underlie this analysis. Most schedulability results [24, 19, 44, 46] are based on the critical instant argument, which defines a worst-case condition for a task. Clearly, a task suffers its worst completion time when it has to compete for the processor (or component in question) with every higher priority task in the system. That is, when it arrives at a time when all other higher priority tasks also arrive. This instant is called the critical instant. Therefore, it is sufficient to look at the completion time of this one instant in order to ascertain the task schedulability. But does this computation really give us the worst-case completion time of a task? In other words, given a task's characteristics, will it ever suffer this completion in reality?

Notice that the critical instant argument clearly ignores the arrival information of tasks and makes the assumption that, sooner or later at least one of the instances of a task will face a critical instant. It can be seen, however, that this is not necessarily true and therefore, the actual worst-case completion time of a task can be less than or equal to the completion time
computed by the critical instant assumption. A simple example will clarify this point: Consider a task-set with two tasks, $T_1$ and $T_2$ whose characteristics are, $a_1 = 0, e_1 = 2, p_1 = 12, d_1 = 10$ and $a_2 = 3, e_2 = 1, p_2 = 12, d_2 = 9$ respectively. Further assume that $T_1$ is the task with the higher priority. Clearly, task $T_2$ will never encounter a critical instant because, its every instance will be ready only 3 units of time after the arrival of $T_1$. Further, $T_1$ needing only 2 units of execution time will complete before $T_2$'s instance is ready. In this scenario, the worst-case response time of task $T_1$ will be 2 and that of $T_2$ will be 1. Ignoring the arrivals and using the critical instant argument will result in $T_2$'s worst-case completion time being computed as 3 and not 1. Therefore, ignoring the arrival times of tasks and using the critical instant argument leads to a pessimistic computation.

Can we tolerate the pessimism inherent to this computation? The answer to this question depends on the environment under consideration, viz., a uniprocessor or a distributed (more generally end-to-end) system. In uniprocessor systems, depending on the assumptions (task independence for example) made, practioners [6] have argued that the cost of finding a more precise measure of the task completion time far outweighs the benefit gained (say, in terms of saved resource utilization). However, there are convincing arguments to the contrary by Tindell in [45]. He discusses scenarios that show the importance of considering the task arrival information in schedulability analysis\(^1\). We believe that the importance can be really felt in end-to-end systems and in uniprocessor systems with dependent tasks and not so much in uniprocessor systems with independent tasks.

\(^1\)Look at the discussion in Chapter 2 about dependent and independent tasks.
Now, let us look at the problem of schedulability analysis in end-to-end systems. The schedulability of a task in an end-to-end system can be reduced to a sequence of uniprocessor schedulability problems provided we are able to compute the characteristics (period and arrival time) of the sub-tasks. Let us assume for now that we have a mechanism to compute the sub-task periodicities (the mechanism will be described in detail later). We don't require the arrival time information if we follow the critical instant argument, since we are going to ignore it anyway. We can use the critical instant argument (ignoring the arrival time $a_{ik}$) to find the worst-case completion times of all sub-tasks $T_{ik} \ (1 \leq k \leq m)$. Clearly, the worst-case completion time of the task $T_i$ is given by the sum of the worst-case completion times computed above. Observe that we have a cumulative measure of pessimistic computations that is bound to be more pessimistic. Therefore, we can see that even if one can tolerate the pessimism inherent in the critical instant argument, in the context of uniprocessor systems, we cannot do so in the context of end-to-end systems.

Before we give a description of the problem we are interested in addressing in this study, we would like to motivate the reader by briefly discussing the source of the problem. In the chapter 1, we mentioned that the kinds of changes (that interest us) that systems undergo, manifest themselves as task execution time changes. A brief discussion of these changes follows.

Note that, the task parameters, deadline and periodicity are dictated primarily by the environment. The arrival time of a task is governed by the environment and the inter-dependence between the tasks. The execution time of a task on the other hand is governed among other things by: (i) the programming language chosen, (ii) the compiler, (iii) the operating system, and
(iv) the processor architecture (e.g., pipeline, cache). Therefore, finding the execution times of tasks is complex and involved [31, 23, 1]. In most cases it is almost impossible to compute a deterministic measure of the execution time of a task. Most research efforts use the worst-case task execution time and not the mean execution time. While this choice can be justified by the fact that the analysis is based on the worst-case scenario, it nevertheless results in an over-design of the system. Also, this assumption can result in poor resource utilization.

Using mean task execution times in the computation does reduce the pessimism but unfortunately we could have cases where the guarantees provided by the schedulability analysis could be invalid (The number of such cases being determined directly by the variance in the computed mean execution time). Therefore, it is necessary to accommodate the variance information along with the mean (for task execution times). For example, if the mean execution time of a task is \( \bar{e} \) and the variance of this mean is \( \sigma \) then it implies that the actual execution time is most likely to lie in the interval \( (\bar{e} - \sigma, \bar{e} + \sigma) \). Schedulability analysis done using the mean execution time will remain valid even when the actual execution time falls between \( (\bar{e} - \sigma, \bar{e}) \). However, the same does not hold for the interval \( (\bar{e}, \bar{e} + \sigma) \). Assuming, the variance is expressed in terms of the mean (which is quite a common practice), we can represent \( \sigma \) as \( fac \times \bar{e} \), where \( fac \) is a constant. If we can extend the analysis done by using the mean execution time to accommodate the possibility of the execution time being scaled by a factor \( sf \) then, it can be seen that this is equivalent to: allowing a variance of \( fac \times \bar{e} \). Where, \( sf = 1 + fac \).

As a system evolves the functionalities of tasks expand, reflecting in
terms of improvement in the data handling of tasks. For example, as an air
traffic control system adapts to new traffic (say from monitoring 8 flights to 12
flights) though the tasks themselves (their code that is) might not change the
data handled by the tasks can change, resulting in an increase in the execution
times of the tasks. This increase does affect the schedulability guarantees made
using the previous execution times. Therefore, what we are interested in is,
finding a factor $sf$ by which the execution times can be scaled (capturing the
data handling change) without invalidating the schedulability guarantees.

A more direct scenario that affects the completion time computation
occurs when the target platform changes. Any analysis performed (to guaran-
tee performance) assuming particular values of task execution times becomes
invalid once the target platform changes. For example, a faster processor could
result in a lower execution time (not invalidating the analysis), but a slower
processor would surely have an adverse affect on the schedulability analysis. As
a system evolves, though in general the overall system is likely to improve, the
performance of individual components (some processors for example) might not
always improve. Another instance where a target platform is in general slower,
arises in the case of prototype building and testing [51].

A last case where we observe the need to do schedulability analysis for
at least two target platforms arises in the area of fault tolerance. It is common
practice to provide fault-tolerant operation by the use of redundant components
(often at least one secondary component). In general, secondary components
provide only a minimal functionality (sufficient to keep the system operational
till the primary is fixed) and therefore tend to be slower. Any schedulability
analysis guarantees provided with the primary component as the target will be
invalid once the system falls back onto the secondary.

From the above discussion we note that, what we need is a measure (will be referred to as the scaling factor for obvious reasons) that in some sense qualifies the schedulability analysis. Provided the task execution times (as a result of the changes described above) satisfy a bound dictated by this measure the schedulability analysis remains valid.

We now discuss the underlying theory derived from past results in the area of real-time systems that is used in this study.

3.1 Scheduling Theory

Research in schedulability analysis has been focused mainly on uniprocessor systems. In recent years the original fixed priority analysis [24] has been considerably extended, relaxing many of the assumptions of the original computation model. Lehoczky et. al.'s [20] efforts to find the worst-case timing behavior of rate-monotonic tasks was the first in this direction. They have subsequently extended this result further, to accommodate any fixed priority task assignment [19]. In this thesis we make extensive use of this result.

The following, is a brief discussion of scheduling under different assumptions about the environment and tasks. A good source of related discussion can be found in [48] and [40].

3.1.1 Static versus Dynamic Scheduling

Static scheduling mechanisms assume complete a priori knowledge about the task characteristics including inter-task dependencies. Such assumptions are
valid in many of today's practical real-time systems [39]. For example, real-
time control of a process control application might have a fixed set of sensors
and actuators, and a well defined environment whose processing requirements
are all known a priori. The operation of the static scheduling algorithm in such
a system involves producing a fixed schedule for what is called a hyperperiod.
The fixed schedule repeats every hyperperiod [48]. For example if the arrival
times of all tasks in a task-set are 0 then the hyperperiod is given by the least
common multiple (LCM) of the task periods. A static scheduling algorithm
assigns a fixed priority to each task that remains unchanged for the lifetime of
the task.

It has been shown by Liu and Layland in their very well known pa-
per [24] that the rate monotonic priority assignment (RMS) guarantees the
schedulability of a task-set (of \( n \) tasks), if the utilization of the task-set is less
than or equal to \( n(2^{1/n} - 1) \). For large \( n \) this bound tends to 0.693. Further,
the RMS was shown to be an optimal static fixed priority assignment when the
deadlines of tasks coincide with their periods. Other significant results in this
direction were, Leung's [21, 22] formulation of an alternative (static fixed) pri-
ority assignment to accommodate tasks whose deadlines are less than or equal
to their periodicities. Audsley et. al. [2] allowed the addition of guaranteed
sporadic tasks and Tindell et. al. and Locke [26, 27] considered the possibility
of tasks having a release jitter.

If a real-time system operates in a dynamic environment where it is
impractical to assume complete knowledge of the processing requirements of
tasks (and their interactions) we use a dynamic scheduling mechanism. In such
a case the chosen dynamic scheduling algorithm is analyzed off-line using the
expected requirements of the dynamic environment. The same algorithm is then used at run-time with the assumption that the run-time behavior of the system does not depart markedly from the expected behavior for which the scheduling mechanism was tested. A static or dynamic scheduling algorithm can be applied in either of the cases, viz., the environment is known or changes dynamically. However, what distinguishes the two is the performance guarantees that can be made about the scheduling mechanism. For example, if the assumption of complete a priori knowledge about the system does not hold then, while a static scheduling algorithm can be used but it will not be able to make any schedulability guarantees.

The earliest deadline first (EDF) scheduling mechanism [24] is the most widely used dynamic scheduling mechanism. EDF runs that task among the task-set that is ready to run and is closest to its deadline. Therefore, as a task nears its deadline its priority relative to other tasks increases. The EDF scheduler was shown to be an optimal dynamic scheduler in the sense that, if there exists a scheduler that can guarantee that all the tasks would meet their deadlines then, so will EDF. A drawback of the EDF scheduler is that in its comparison of tasks, $T_i, T_j$, with deadlines, $d_i, d_j$, there is no regard for their execution times, $e_i, e_j$. Therefore, even if the two tasks' deadlines differ by a small amount ($d_i - d_j = +\epsilon$), $d_i$ will be chosen to run instead of $d_j$ even if their execution times differ by a large amount ($e_i << e_j$). The least laxity first (LLF) scheduler [29] uses a different basis for priority assignment that partly answers the need to accommodate the execution times of tasks. The laxity of a task, $T_i$ is the difference ($d_i - e_i$), between the deadline and the execution time of a task. It essentially captures the room for meeting the deadline of a
task. LLF scheduler has also been shown to be an optimal dynamic scheduler.

In summary, the choice of a particular scheduling mechanism is governed by such considerations as: (i) The assumptions that can be made about the environment (static vs. dynamic), (ii) the guarantees provided by the scheduler being considered, (iii) the cost in terms of computational overhead of the scheduler and (iv) the constraints on the task characteristics (e.g., deadline ≤ period of tasks).

### 3.1.2 Relationship between deadline and period

The classical scheduling result by Liu and Layland [24] is built on the assumption that the deadlines of tasks are equal to the periods of tasks. In other words, an instance of a task is required to be completed before its next instance is ready. As already mentioned, the rate-monotonic priority assignment (RMS) gives an optimal fixed priority scheduling mechanism for this scenario.

However, if the deadlines of tasks are allowed to be less than or equal to their periods (i.e., $d_i \leq p_i \ \forall T_i$) then the optimality of RMS does not hold. As shown by Leung and Whitehead in [22], the deadline monotonic scheduling (DMS) mechanism is an optimal for this scenario. The DMS assigns the highest priority to the task with the shortest deadline. This DMS scheme is optimal in the sense that if any fixed priority scheme can schedule a task-set then so can the DMS scheme. One should not confuse the deadline monotonic scheduler with the EDF which is a dynamic scheduling mechanism where a task's assigned priority can change dynamically. A special case of this scenario occurs when the deadlines of tasks are a constant factor of their periods. In other words, $\forall T_i, \ d_i = \kappa \times p_i$, where $\kappa \leq 1$. Note that both RMS and DMS would end up
being the same in this case.

The third scenario occurs less commonly in real-time applications (more common in imprecise computation [25, 36, 37]), where the deadlines of tasks can be beyond the end of their periods. This scenario was first studied by Lehoczky [20], where he considered the possibility of $\kappa$ (in the formulation of the previous paragraph) being greater than 1. He showed that for a value of $\kappa = 2$ the utilization bound of RMS increases from 0.693 to 0.811. He reported simulation studies that show a more promising (close to 1.000) increase in the achievable utilization.

### 3.1.3 Precedence Constraints and Resource Sharing

An inherent characteristic that governs current complex real-time systems is the cooperation of tasks to achieve the goal of an application. Such cooperation can be captured by various types of communication semantics. Depending upon the chosen semantics, tasks experience precedence constraints or blocking or both. Blocking occurs due to the use of a synchronization mechanism (like priority inheritance protocol [33]) to regulated resource sharing. Similarly the use of critical sections to achieve concurrency control (Sha et. al. [34]) can result in blocking. An alternative to using a concurrency control mechanism for regulating resource accesses is to impose strict order on these accesses. Such an order can be captured by imposing precedence constraints on tasks that share the same resource. As was shown by Tindell et. al. in [45] and will be explained in more detail in chapter 5 of this thesis, these two scenarios can be captured by considering tasks to have arrival time characteristic in addition to execution time, period and deadline.
3.2 Uniprocessor Schedulability

Most schedulability results [24, 19, 46] are based on the critical instant argument, which defines a worst-case condition for a task. As noted before, worst-case completion time computation is the crux of schedulability analysis. The critical instant argument gives us a situation under which a task will undergo its worst possible completion:

**Lemma 3.2.1** The worst-case completion time for task $T_i$ occurs when it arrives at a critical instant, $a_1 = \ldots = a_i = 0$.

This lemma tells us that any instance of a task that arrives at a point in time when all higher priority tasks also arrive suffers the worst completion time. We still have to compute this completion time. The following equation gives a mechanism for this computation:

$$W_i = \text{the smallest } X \text{ for which } \left( \sum_{j=1:i-1} e_j \left\lfloor \frac{X}{p_j} \right\rfloor + e_i \right) \leq X$$

The above equation can be viewed in terms of demand and supply. The term $\sum_{j=1:i-1} e_j \left\lfloor \frac{X}{p_j} \right\rfloor$ captures the demand for processor time from all instances of tasks with priority higher than $i$ over $X$ units of time. Therefore, the fraction in the above formula gives the ratio of the demand to the supply. The shortest supply $X$ for which the demand is met, i.e., $\text{supply} \geq \text{demand}$, gives the completion time of the task $= W_i$. Further, if this value $W_i$ is less than or equal to the deadline of the task ($D_i$), then the task meets its deadline.
3.3 Other Relevant Work

The area of end-to-end scheduling is a relatively new area in real-time systems. Prominent work in this area has been reported by Bettati in his thesis [4]. As he showed in [4], the problem of finding an optimal scheduler for scheduling end-to-end tasks is NP-complete [13]. To this end, he proposed and analyzed heuristic approaches to solving this problem. The schedulability test he uses to test his heuristic schedulers is based on the critical instant argument. As was discussed before, this results in a pessimistic evaluation of the scheduler. It is therefore possible that he rejected heuristics that did not perform well under the pessimistic test but would in fact have been able to guarantee schedulability.

Other ongoing research on this problem was reported by Etamadi in [7]. He proposes to enhance the analyzability of end-to-end systems without making constraining assumptions that restrict resource utilization. Further, he proposes building robust application models that would allow enhancements like synchronization, communication. Related work can also be found in [14, 30].

Finally, on the problem of admission control of RT channels [28, 9]. The Tenet group’s Ferrari et. al. were the first to deal with this problem extensively. The principle they followed [8, 9] in the design of an admission control scheme is based on verifying, whether the resources available on the path of the newly requested RT channel are sufficient even in the worst possible case, to

1. provide the new RT channel with the QoS it needs and,

2. allow the guarantees offered to all the existing RT channels to continue being satisfied.
The above verification depends upon the kinds of QoS parameters allowed. The most important QoS parameter of concern to real-time system designers is meeting a latency bound (deadline). We restrict our interest to this parameter. There are two tests that are relevant in this context:

- **Schedulability Test**: Does the addition of the new channel to the already established channels using this link cause either the new channel or one of the already established channels to miss their deadline?

- **Buffer Space Test**: Is the available buffer space at the link sufficient to allow the messages of the new channel to be stored for a length of time equal to the delay faced by the channel at this link?

Different approaches to the admission control problem (in real-time systems) will differ in the way the above two questions are answered. Therefore, a study in admission control reduces to the study of these tests. The buffer space test has been successfully addressed by the Tenet group [9]. We concentrate mainly on the schedulability test because it is our belief that there is room for improvement here. In particular, there are many situations that have not been considered in this context.
Chapter 4

Problem Statement and Description

4.1 Scalability of Uniprocessor Systems

The uniprocessor scalability problem can be formally defined as follows:

**Problem Definition 4.1.1** Given a task-set $T$ consisting of $n$ tasks, and a subset $S$ of $T$. Find the maximum common scaling factor by which the execution times of each of the tasks in the subset $S$ can be scaled, without affecting the schedulability of the task-set $T$.

As described in the previous chapter, the schedulability of tasks running on a uniprocessor can be determined by lehoczky's [19] schedulability test. The scalability problem now involves extending this test to compute the scaling factor.

4.2 Scalability of End-to-End Systems

The problem of interest here is the "Scalability of task-sets in end-to-end real-time systems". The problem can be looked at from two different viewpoints: (i) The first viewpoint stems from assuming the scaling to occur as a result of a change in one or some of the components in the system; (ii) The second
viewpoint stems from assuming the scaling to occur as a result of a change in the functionality of some or all of the sub-tasks in the system.

4.2.1 Component Change

A change in a component $R_r$ can result in a gain or a loss in the speed of processing for the sub-tasks running on it. Clearly, if there is a gain in speed of a component then this will not have any adverse affect on the completion times of sub-tasks running on it. However, if the component is replaced by a slower one then it will affect the completion times and hence the schedulability of the sub-tasks running on it. The problem of interest therefore is, to find the maximum factor by which all the sub-tasks on a particular component $R_r$ can be scaled such that the schedulability of the task-set (comprising all $n$ tasks that is) is unaffected.

In the following formulation we assume that a single component is undergoing a change. We can however, generalize it to a sub-set of components. The problem of scaling occurring as a result of a component change can now be formally posed as:

**Problem Definition 4.2.1** Given a task-set $T$ of $n$ end-to-end tasks executing in a system of $m, (m \geq 1)$ components, find the optimal scaling factor $1/sfc$ (corresponding to a maximum $sfc$) with which the processing speed of a given component $r$ can be scaled (down), without affecting the schedulability of the task-set.

In other words, we are interested in the maximal component change the task-set can survive. The reason for representing the scaling factor as a
reciprocal will become obvious once we realize that a lowering in processing speed of a component will reflect as an increase in the execution times of sub-tasks running on the component. For example, if the speed of the component is $S$ (instructions per unit time) then an execution time requirement of a sub-task $T_{ik}$ being $e_{ik}$ (time units) implies that the number of instructions that the sub-task requires to execute are $S \times e_{ik}$. If the processing speed is scaled down by $1/sfc$ (implying that $sfc \geq 1$) then, we have the new speed $S' = S \times 1/sfc$. Therefore, the amount of time it would take to execute $S \times e_{ik}$ instructions\footnote{Assuming that a change in the component is such that the same code is able to run on the new component} is given by:

$$
e_{ik}' = \frac{S \times e_{ik}}{S'} = \frac{S \times e_{ik}}{S \times 1/sfc} = sfc \times e_{ik}$$

In this formulation, we assume that all sub-tasks that execute on component $r$ will be equally affected. That is for all sub-tasks $T_{jr}$ ($1 \leq j \leq n$) running on component $r$ their execution times as a result of the change would become $sfc \times e_{jr}$. The next perspective to the scaling problem however, allows for the possibility that only a subset of the sub-tasks running on a component are affected as opposed to all sub-tasks being affected.

4.2.2 Task Changes

As opposed to a change in one or more components, we can envision one or more sub-tasks being affected by a change. For example as a system evolves,
to encompass more functionality, some of the sub-tasks (their code that is) need to be modified (enhanced), resulting in an increase in their execution times. Alternatively, enhancements could come in the form of increased data handling, manifesting as an increase in the execution times of tasks (as before we do not consider decreases because they do not violate prior schedulability guarantees). The problem of scaling occurring as a result of task changes can now be formally posed as:

**Problem Definition 4.2.2** Given a task-set $T$ of $n$ end-to-end tasks executing in a system of $m$, ($m \geq 1$) components, find the maximum scaling factor, $sft$ with which a subset of the sub-tasks (say $S : \{T_{ik}, \text{ where } 1 \leq i \leq n; 1 \leq k \leq m\}$) execution times can be scaled, so that the task-set $T$'s schedulability remains unaffected.

As it will be clear from the following discussion, solving the end-to-end schedulability problem can be reduced to solving $m$ independent (deemed independent by an important transformation to be described later) single component schedulability problems. In other words, solving the above formulated scalability problem for a subset $S$ will become equivalent to solving $m$ single component scalability problems on each of the subsets $S_1, S_2, \ldots, S_m$. A subset $S_r$ contains all sub-tasks $T_{ir}, (\forall i)$ belonging to $S$. If for a particular component $r$, there are no sub-tasks $T_{ir} (\forall i)$ in $S$ then we set the corresponding set $S_r = \phi$ (null set).
We can observe one step that is common to the above two formulations, viz.,
determining the schedulability of the given task-set $T$. This is the initial step
to be done in solving both these problems. Note that, if a task-set $T$ is un-
schedulable to start with then, any adverse change either to a component or
to a subset of the sub-tasks is only bound to make the situation worse. The
problem of interest can therefore be posed as:

**Problem Definition 4.2.3** Given a task-set $T$ of $n$ end-to-end tasks executing
in a system of $m$ components, find if the task-set is schedulable.

In order to find the schedulability of end-to-end task-set, we have to find
if each end-to-end task in turn will be schedulable, i.e., meet its deadline when
the individual sub-tasks compete for processing on their respective components.
Therefore, for each task we have to find its worst-case completion time which
can then be compared against its deadline. The worst-case completion time of a
task $T_i$ can be computed by assuming that all its sub-tasks simultaneously suffer
their worst-case completions. The worst-case completion time of the task ($T_i$),
is then given by the sum of the worst-case completion times of the individual
sub-tasks ($T_{ik}$). For a given sub-task $T_{ik}$, executing on the component $R_k$, the
information we need to find its worst-case completion time is:

- The arrival time of all sub-tasks $T_{jk}$ ($j \leq i$)$^2$, which are of higher priority
  than $T_{ik}$ and are running on the same component, $R_k$.

$^2$Unless otherwise specified, the arrival time of a sub-task $T_{ik}$ implies the arrival of its
first instance
• The periodicity of all sub-tasks $T_{jk}$ ($j \leq i$), which are of higher priority than $T_{ik}$ and are running on the same component $R_k$.

Notice that when, $i = n$ we have to find the arrival time and periodicities of all sub-tasks in the system to determine the schedulability of the task $T_n$. Therefore, we need a mechanism by which we can derive these two parameters (since these are not given a priori). Note that, only the first sub-task of any task is truly periodic. The arrivals of the consecutive instances of any sub-task $T_{ik}$, ($1 \leq i \leq n; 1 < k \leq m$) are dictated by the completion times of the sub-task preceding it, i.e., $T_{i,k-1}$. These completions are obviously non-periodic and so are the arrivals of sub-task $T_{ik}$. We however can impose a periodicity on these sub-tasks by a proper justification. The phase adjustment mechanism [51], is one such mechanism that derives sub-task arrival times and also their periodicities. The term phase here is used to denote arrival time.

Imposing a period on the arrivals (of consecutive instances that is) of a sub-task $T_{ik}$ ($1 < k \leq m$), implies that, even if the preceding sub-task $T_{i,k-1}$ does finish at a particular time$^3$ (say $F_{i,k-1}$), the sub-task $T_{ik}$ will not be ready immediately. A finite amount of time (say $W_{i,k-1} - F_{i,k-1}$)$^4$ has to elapse before the sub-task $T_{ik}$ is ready to execute. It is necessary to limit this finite amount of wait time in the sense that, if it is too large then it could hurt the utilization of the component $R_k$. This is due to the fact that, while the sub-task is being intentionally delayed, the component $R_k$ could be idle. On the other hand this delay must be large enough to be able to accommodate all possible finish

---

$^3$All references to time are relative to $t = 0$, unless otherwise specified

$^4$Here, $W_{i,k-1}$ is a constant for the task $T_{i,k-1}$; therefore, the delay is a variable for each instance of $T_{i,k-1}$
times (of its various instances) of task $T_{i,k-1}$. Clearly therefore, in the limiting condition ($\text{delay} = 0$) $W_{i,k-1}$ must be given by the worst-case completion time of the sub-task $T_{i,k-1}$.

An effect of this adjustment is that a sub-task $T_{i,k}$ will always be ready (or arrive) after a constant amount of time from the arrival of the preceding sub-task $T_{i,k-1}$. Therefore, knowing the arrival time of the sub-task $T_{1}$, we can find the arrival of the sub-task $T_{2}$, knowing which we can find the arrival of $T_{3}$ and so on. It should be clear to the reader that the above adjustment also allows all sub-tasks belonging to a task to inherit its period.

What the above adjustment has afforded us is, the ability to treat each of the components independently, provided we are able to find the terms $W_{i,k}$ ($\forall i, k$). Observe that we have all the information about sub-tasks $T_{i}$ ($1 \leq i \leq n$), running on the first component, $R_{1}$ (That is, we have their arrival times, periods and execution times). Now the problem we wish to solve is finding the worst-case completion times of these tasks. Once we find these worst-case completion times we have all the information about sub-tasks $T_{i2}$ ($1 \leq i \leq n$), running on the second component, $R_{2}$ and so on. The problem of interest can therefore be formally posed as:

**Problem Definition 4.2.4** Given a task-set $T$ of $n$ tasks executing on a single component, find the worst-case completion times of all tasks in the task-set.

Observe that this problem is similar in sense to the schedulability problem solved by Lehoczky [19] (refer to Chapter 3). However, while his solution using the critical instant argument can be used in the context of uniprocessor
systems, we cannot use it here (in the context of end-to-end systems that is). Finding a solution to this problem is one of the results of this thesis.

Now that we described a mechanism to test whether a given task-set is schedulable, we have answered the question of whether there exists a scaling factor as defined by the two problems, 4.2.1 and 4.2.2. Clearly, if the tasks are so stringent that any increase in the execution times of the sub-tasks cannot be tolerated, then the scaling factors $s_{fc}$ (as defined in problem 4.2.1) and $s_{ft}$ (as defined in problem 4.2.2) will both be equal to 1.0.

The end-to-end schedulability problem has been reduced to $m$ single component worst-case completion time computation problems and not $m$ single component schedulability problems. Therefore, we cannot talk about extending a single component’s schedulability, unless we derive the sub-task deadlines. A major research issue in end-to-end scheduling has been the derivation of sub-task deadlines. Given an end-to-end task’s deadline the problem of finding an optimal\(^5\) division of this deadline among the sub-tasks is intractable [15] (NP-complete [12]). This result has prompted a heuristic approach [4, 15, 30], two such heuristics being: (i) divide the task’s slack\(^6\) equally among the sub-tasks; (ii) divide the task’s slack among its sub-tasks in a weighted proportion of their execution times.

The above two heuristics vary mainly in their sensitivity to the execution times of tasks. For example, the second heuristic is built on the assumption that the shorter a task’s execution time requirement, the more likely it will have

---

\(^5\)In the sense that, if there exists a division that would help the task meet its deadline then the mechanism should find it

\(^6\)The slack of a task is given by the difference between its deadline and its execution time
its requirement met and therefore the lower is the slack assigned to it. The first heuristic is built on the assumption that the priority inherited by a sub-task has a greater impact on its ability to meet its execution time requirement than its execution time itself. Thus the slack is divided equally among all sub-tasks. This allows us to reduce the end-to-end scalability problem to \( m \) single component scalability problems.

Now, finding the common scaling factor is a simple matter of finding the minimum of the \( m \) scaling factors (each corresponding to one component). The problem of interest therefore is the single component scalability problem, which can be formally defined as follows:

**Problem Definition 4.2.5** *Given a schedulable task-set \( T \) of \( n \) tasks executing on a single component and a subset \( S \) of \( T \), find the maximum scaling factor \( s_f \) with which all tasks in \( S \) can be scaled without violating the schedulability of any of the tasks in \( T \).*

Now, we can observe that solving the two problems 4.2.1 and 4.2.2 amount respectively to:

- Solving the single component scalability problem (4.2.5) with \( S = T \).

- Solving the \( m \) single component scalability problems and taking the minimum among these scaling factors.

We can now summarize this discussion on end-to-end scalability by noting that, solving this problem entails finding solutions to the two problems, 4.2.4 and 4.2.5.
4.3 Admission Control of RT Channels

The problem of admission control of real-time (RT) channels was first investigated by Ferrari et. al. [9] at the Tenet group. Admission control is the mechanism by which multiple real-time connections can simultaneously share the resources of a packet switching network without resulting in congestion. Further, the connections are guaranteed a particular quality of service (QoS) that is initially (at connection set up) agreed upon. Admission control comes into play when a new RT channel is being requested. An RT channel (or a connection request) is accompanied with a QoS list that describes the requirements of this connection. Popular QoS requirements in the literature of distributed real-time systems are - throughput, latency (or deadline), packet loss tolerance [28, 10, 35] etc.

The mechanism used to determine the admissibility of a real-time channel involves verifying at each intermediate link (along the path) in turn whether the RT channel's QoS requirements can be guaranteed. If a channel's requirements can be met at each of the intermediate links then we can accept the channel. If however, the channel's requirements cannot be met at any of the intermediate link then we can reject the channel. In fact the first such link that deems the channel inadmissible is sufficient to confirm that the channel would not be admissible.

In order to test whether a channel's requirements will be met at an intermediate link we have to know its deadline and its period at that link. Finding the period is straightforward according to the phase adjustment mechanism. However we do have to derive the deadline of the RT channel at intermediate links. Since the service time of the channel on each of the links is the same
one way to derive the deadlines would be to divide the slack of the RT channel equally among the intermediate links. However, if one wishes, one can use a more sophisticated heuristic [15, 4] to derive these deadlines. This reduces the problem of finding the admissibility of an RT channel to be equivalent to solving the admissibility at each of the intermediate link. From here onwards when we refer to the admissibility of an RT channel we mean its admissibility at an intermediate link.

Now, the question that admission control has to answer when accepting a new connection can be broadly phrased as:

**Problem Definition 4.3.1** *Given the QoS requirements of a new RT channel is it possible to accept this channel without violating the QoS guarantees made to RT channels that have already been accepted?*

To summarize this chapter, we have defined four problems of interest:

- The uniprocessor scalability problem (4.1.1),
- The single component schedulability problem (4.2.4),
- The single component scalability problem (4.2.5), and
- The problem of admission control of RT channels (4.3.1).

The next chapter discusses the first of these problems. Note that, the third problem in the above list is different from the first in that, it involves tasks whose arrival times cannot be assumed to be zero (as in the critical instant assumption).
Chapter 5

Scalability in Uni-processor Environments

As discussed in Chapter 1, a host of schedulability related issues translate into a more general problem called the scaling problem. Observe that the scaling factor as defined in the problem statement attempts to capture a common factor by which a sub-set of tasks belonging to a task-set can be scaled together. In our first attempt at this problem we made an assumption that the sub-set $S$ is the same as the task-set $T$. That is, we were interested in scaling the complete task-set as opposed to a sub-set of tasks. A solution to this problem can be found in [52]. The following discussion however considers the general scaling problem as stated in Problem 4.1. The model assumed is the uniprocessor model described in chapter 2. We repeat the problem statement here and give a discussion about the possible approaches to the solution followed by the details of the solution approach we have taken.

5.1 Problem Statement

- Given a task-set $T$ consisting of $n$ tasks, and a subset $S$ of $T$. Find the maximum common scaling factor by which the execution times of each of the tasks in the subset $S$ can be scaled, without affecting the schedulability of the task-set $T$. 
The particulars about the scheduling algorithm used to schedule these tasks have not been specified in order to keep the problem general. The choice of scheduler can be either a dynamic scheduler (like earliest deadline first) or a fixed priority static scheduling algorithm. If the chosen scheduler is the latter then the tasks are assumed to be numbered (decreasing order) according to their priorities as dictated by the scheduler. The term, scaling factor is used to refer to a scale up in the execution times and not a scale down. It can be shown that if the execution time of a task is reduced then the schedulability of the task (and other lower tasks) will remain unaffected.

The use of the term, "maximum" needs some explanation here. The scaling factor we desire is one that cannot be improved upon. In other words, given that \( sf \) is the maximal scaling factor and \( \epsilon \) is an infinitesimally small quantity. Using \( sf \) to scale the tasks in \( S \) would not affect the schedulability of the task set whereas using \( sf + \epsilon \) as the scaling factor results in at least one of the tasks in \( T \) being unschedulable.

5.2 Discussion of Possible Solution Approaches

We concern ourselves mainly with a static fixed priority scheduling mechanisms because the above problem has a rather trivial solution when we assume a dynamic preemptive scheduling algorithm (say EDF). It is possible to find a feasible schedule using a dynamic scheduling mechanism provided the following condition holds for the utilization [24]:

\[
U = \sum_{\forall j \in T} \frac{e_j}{P_i} < 1
\]
If the utilization of the task-set is greater than 1, then clearly the task-set is not schedulable by any dynamic scheduling mechanism and further the question of scaling the tasks is not relevant anymore. The above condition is both a necessary and sufficient condition for EDF to be able to guarantee the schedulability of the task-set. Therefore, meeting the above condition ensures the existence of a scaling factor. Now, given such a task-set we can scale the tasks in the sub-set such that the new utilization $U'' = 1$.

$$U'' = \left( \sum_{v_j \in S} \frac{s_{edf} \times e_j}{p_j} \right) + \left( \sum_{v_j \in (T-S)} \frac{e_j}{p_j} \right)$$

$$= s_{edf} \times \left( \sum_{v_j \in S} \frac{e_j}{p_j} \right) + U - \left( \sum_{v_j \in S} \frac{e_j}{p_j} \right)$$

$$= (s_{edf} - 1) \times \left( \sum_{v_j \in S} \frac{e_j}{p_j} \right) + U$$

The scaling factor of interest therefore is when $U'' = 1$, given by:

$$s_{edf} = \frac{1 - U}{\sum_{v_j \in S} \frac{e_j}{p_j}} + 1$$

This factor is not valid in the case of static fixed priority preemptive scheduling algorithms because the above condition on utilization (i.e., $U \leq 1$) does not necessarily guarantee the existence of a fixed priority scheduling algorithm. A similar bound does exist for the rate monotonic scheduler (RMS: a fixed priority scheduling mechanism), under the assumption that the deadlines are equal to periods: $n(2^{1/n} - 1)$. The rate monotonic priority assignment is known to be optimal in this case [20]. Further, the total utilization of the task-set being less than or equal to $n(2^{1/n} - 1)$ is a sufficient (not necessary)
condition for optimality. In other words the above condition guarantees that a rate monotonic priority assignment will result in the task-set being schedulable. Therefore, one can say that a scaling factor $s_{frms}$ (following the same derivation as above but replacing the utilization bound $n(2^{1/n} - 1)$ for 1) given by the following equation does not violate the schedulability of the task-set.

$$s_{frms} = \frac{n(2^{1/n} - 1) - U}{\sum_{v_j \in S} \frac{e_j}{p_j}} + 1$$

The above computation of the scaling factor does give us a valid factor in the sense that using this factor to scale tasks does not violate the schedulability of the task-set. However, it is not necessarily optimal in the sense that the resulting utilization bound is not a tight bound. In order to understand why this bound is not tight one has to look more carefully at the meaning of the schedulability bound, $n(2^{1/n} - 1)$. This bound is only a sufficient and not a necessary condition for the task-set to be schedulable by the RMS mechanism [20]. Therefore it is possible that a task-set does not meet this schedulability bound and yet is schedulable by the RMS mechanism. Therefore we observe that a more precise analysis is necessary to get the maximal scaling factor.

A second observation one has to make about the above scaling factor computation is that, the computation derives its validity from the fact that the rate monotonic priority assignment is optimal when deadlines and periods of tasks coincide. If this condition (deadlines equal periods) does not hold then, we can no longer use the above result. If the deadlines of tasks are known to be less than their periods, then the deadline monotonic priority assignment (DMS) is known to be optimal [22]. However, there is no known sufficient condition
on the total utilization. Therefore, in order to compute the scaling factor we have to do a more precise analysis of the task-set.

As a special case of the scaling problem, if the sub-set $S$ is same as $T$ then the scaling factor would be a simple reciprocal of the utilization in the case of EDF (i.e., $s_{f_{	ext{ef}}}$). Similarly, in the case of RMS, the scaling factor using the approach above would be, $s_{f_{	ext{rms}}} = \frac{n^{2^{1/n}-1}}{U}$ (this is not optimal, as already discussed above).

In the following, we give the algorithm to find the maximal scaling factor when an arbitrary (RMS and DMS being two instances) fixed priority assignment is used. Before the details of the mechanism are presented we would like to intuitively motivate the idea behind it. We consider the case of scaling all tasks to present the motivation. Since we are interested in the common scaling factor, one approach would be to consider a successive approximation technique as taken by [6]. Incremental factors are used to scale tasks and perform a schedulability analysis to confirm if the increment is acceptable. Clearly, such a technique would be expensive.

An alternative approach would be to incorporate the scaling factor computation into the schedulability test. This is the approach we have taken. The schedulability test we use is the one proposed by Lehoczky in (refer to Chapter 2). The idea behind Lehoczky's schedulability test is to ascertain the schedulability of each task in turn starting from the highest priority task. The schedulability of each task involves considering all tasks that are of higher priority than itself. Therefore, the schedulability test of a task $T_i$ can be interpreted as follows: To ascertain whether task $T_i$ will meet its deadline while continuing to honor the timing requirements of all higher priority tasks. Note that the test
does not consider whether the higher priority task meets its deadline. It only makes sure that any higher priority task will not wait for the processor while a lower priority task is using it. In other words, it ensures that in every $p_j \ (j < i)$ time units the task corresponding to task $T_j$ would get $e_j$ units of the processor's time. It is possible for example that, a higher priority task $T_j$ gets its last unit of required execution time between $d_j$ and $p_j$ (note $d_j \leq p_j \ 1 \leq j \leq n$), thus meeting its demand\(^1\) but not its deadline.

On the same lines our approach to finding the scaling factor attempts to find the scaling factor for each task in turn starting from the highest priority task. The scaling factor ($s_f^i$) obtained with respect to a task $T_i$ therefore guarantees that the task $T_i$ would meet its deadline continuing to honor the scaled (scaled by $s_f^i$) requirements of all higher priority tasks. In other words, $s_f^i$ is the factor with which the execution times of all tasks with priority greater than $T_i$ and including $T_i$ can be scaled without $T_i$ missing its deadline even after accommodating all the scaled higher priority tasks. The required scaling is then the minimum of all computed scaling factors $s_f^i$. A more detailed treatment of the solution follows.

### 5.3 Details of the Approach Taken

An analogy can be drawn between the computation of the scaling factor $s_f^i$ and assessing the schedulability of the task $T_i$. In order to assess the schedulability of task $T_i$ we compute the worst-case completion time of task $T_i$ and compare it against its deadline. This computation takes into account the execution time

\(^1\)It will not wait for the processor while a lower priority task is using it
demands of higher priority tasks (but is independent of the higher priority
tasks' ability to meet their deadlines). Similarly in the computation of the
scaling factor with respect to task $T_i$, we only account for the execution time
(scaled) demands of the higher priority tasks and not the ability of these tasks
to meet their deadlines.

We find such scaling factors for all tasks and the required scaling factor
is the minimum among these, i.e., $sf = \text{Minimum}(s_f')$. Note that each of the
scaling factors $s_f'$ only considers the schedulability of task $T_i$ and any scaling
factor that is less than $s_f'$ will continue to guarantee its schedulability. Since
we are interested in a common scaling factor, the lowest of the scaling factors
$s_f' \ h \leq i \leq n$ (The index $h$ is defined below). In the following paragraphs,
we present the details of the technique for the general scaling problem and a
proof of its operation.

We make use of the schedulability test described in [19, 6] to find the
worst-case response times of tasks.

Note that in the previous section we assumed that $T = S^2$ in order to
simplify the explanation of the solution. In this context we gave a definition
of $s_f'$ that needs a slight refinement to adapt to the case that the set $S$ is not
necessarily equal to $T$. The scaling factor $s_f'$ is the factor with which the tasks
in the set $S$ with priorities higher than $T_i$ can be scaled without affecting $T_i$'s
schedulability, while continuing to honor the demands of all tasks with priority
higher than $T_i$. The requirements of higher priority tasks include both: (i)
the requirements of higher priority tasks that are not included in $S$ and (ii)

\footnote{We assume that the tasks in $S$ are sorted in a non-increasing order of their priority}
the scaled (scaled by \( sf^i \) that is) requirements of higher priority tasks that are included in \( S \). There are two important observations to be made:

- In the computation of the scaling factor \( sf^i \) the task \( T_i \) is not necessarily a member of \( S \). This is because there are tasks in \( T \) that do not belong to \( S \) whose schedulability could be affected by the scaling of tasks in \( S \). And we cannot ignore them in computing the desired scaling factor.

- The number of scaling factors to be computed is equal to \( n - h \). The number of tasks in \( T \) of priority less than the highest priority task in \( S \). Clearly from the definition of \( sf^i \) in the above paragraph, we see that for all tasks \( T_i \) whose priority is greater than the any in \( S \), \( sf^i \) is undefined.

The given sub-set \( S \) is assumed to be sorted by the decreasing order of priorities. Let \( T_h \) be the highest priority task (first task) in \( S \). For each task \( T_i \) where \( h \leq i \leq n \) (starting from \( i = h \) and counting up), we find the scaling factor by which all tasks in \( S \) whose index is \( < i \) can be scaled, while continuing to maintain \( T_i \)'s schedulability (i.e., meeting its deadline and the demands of all tasks with priority higher than \( T_i \) are honored).

Since we make the critical instant assumption, only the first task instance of any task \( T_i \) needs to be considered for its schedulability [19]. Note that only higher priority tasks affect the schedulability of a task, because lower priority tasks will be preempted. We consider the execution profile of task \( T_i \) \((i \geq h)\) along with all higher priority tasks \( T_j \) where \( j < i \). In Figure 1, the first continuous block (no idle time in between) of used time is represented as

---

3Task \( T_h \) is the highest priority task that needs to be scaled.
$U_1$. The notation $U_1$ is also used to represent the length of this block. The $j^{th}$ such used time block is represented as $U_j$. Further, $U_{j,L}$ and $U_{j,R}$ represent the left and right boundaries of the block $U_j$ (i.e., $U_j = U_{j,R} - U_{j,L}$) respectively, relative to the start time of consideration (i.e., $U_{1,L}$, which can be assumed without loss of generality to be zero). The first task instance of $T_i$ (refer to Figure 5.1) completes at a point $U_1$ units of time after it has arrived, with all higher priority tasks also arriving at $U_{1,L}$, the same instant as $T_i$ arrives - critical instant.

![Figure 5.1: Task $T_i$'s Execution Profile](image)

The blocks of execution between the points $U_{1,R}$ (The earliest point in time after the completion of task $T_i$ at which the processor becomes idle) and $d_i$ (deadline of $T_i$) are: $U_2, U_3, \ldots, U_k$ (There are $k$ used time blocks in all). These blocks represent the higher priority tasks that would have to be accommodated if we want to push the completion time of $T_i$ towards $d_i$. Each block of used time is divided into marked and unmarked sub-blocks. A sub-block of block $U_j$ is said to be marked if the execution that spans it belongs to a task (or tasks) that belong to the sub-set $S$. A marked sub-block, denoted as $U^p_j$, indicates the $p^{th}$ marked sub-block in $U_j$. There are $k$ such marked sub-blocks in all. The
way the scaling factor, $s f^i$ for task $T_i$ is computed is as follows:

$$s f^i = \max_{1 \leq m \leq k-1} s f_m$$

where

$$s f_m = \frac{\sum_{1 \leq j \leq m} \left( \left( \sum_{\forall i} U_j^i \right) + (U_{j+1,L} - U_{j,R}) \right)}{\sum_{1 \leq j \leq m} \sum_{\forall i} U_j^i}$$

$s f_m$ in the equation above is the factor which when used to scale the execution times of all tasks in $S$ of higher priority than $T_i$, will be able to stretch the completion time of task $T_i$ at most till $U_{m+1,L}$. The first term in the numerator (same as the denominator) is the total of the execution times of tasks in $S$ that are considered for scaling at this point (i.e., tasks in $S$ whose priority is higher than $T_i$). The second term in the numerator is the total idle time that these tasks are being scaled to consume. Therefore the right hand side of this equation in a simplified sense can be viewed as $\frac{\text{used time} + \text{idle time}}{\text{used time}}$.

Observe that, each $s f_m$ is a valid scaling factor in the sense that it does not result in $T_i$ missing its deadline. Since we are interested in the maximum scaling factor, the maximum among these valid factors is the required solution. The resultant scaling factor $s f^i$ is therefore the maximum scaling factor w.r.t task $T_i$. However, from the definition of $s f^i$ one can see that the possibility of a higher priority task missing its deadline is not accounted for in this factor (only its demand is accounted for). Therefore, this scaling factor is valid only in the context of task $T_i$. In order to find a common scaling factor for the sub-set $S$ now, we have to find the minimum among all $s f^i$ ($h \leq i \leq n$).
To understand why the minimum has to be taken, note that w.r.t task \( T_i \) \((h \leq i \leq n)\) any scaling factor value less than \( sf^i \) will still continue to be valid. However, w.r.t some other task \( T_j \) \((h \leq i \leq n)\), where \( sf^j < sf^i \), \( sf^i \) will not serve as a valid scaling factor. Observe that \( sf^j \) will surely serve as a valid scaling factor w.r.t both \( T_i \) and \( T_j \). If we generalize this observation, it is clear why the minimum is the required solution.

The complete algorithm to compute maximal scaling factor is given below.

1 Algorithm Scale\_Factor\((T, S)\)

Parameters: \( T \) is the given task-set which is schedulable. \( S \) is the sub-set whose scaling factor is desired. \( S \) is assumed to be sorted in the increasing order of their priorities. Assume that \( T_h \) is the highest priority task in the sub-set \( S \).

Step 1: For \((i = h; i \leq n; i++)\)

1.1 Compute first approximation for the completion time of task \( T_i \)'s first job:

\[
\text{compl}_0 = \sum_{j=1}^{i} e_j
\]

1.2 Calculate the next approximation for completion time:

\[
\text{compl}_{i+1} = e_i + \sum_{j=1}^{i-1} \left[ \frac{\text{compl}_i}{p_j} \right] e_j
\]

1.3 If \((\text{compl}_{i+1} > d_i)\) then The job missed its deadline:

Exit(-1);
Step 1.4: If \((compl_{t+1} \neq compl_t)\) then we have not arrived at the completion time of the task, so, goto Step 1.2;

Step 1.5: The completion time for the job is \(compl_t\);

Step 1.6: Fit higher priority task instances that would arrive between the points \(compl_t\) and \(d_i\). The scheduling points are \(U_{2L}, U_{3L}, \ldots, U_{kL}\). where, \(U_m = U_{mR} - U_{mL}\) denotes the \(m^{th}\) used time block (refer to Figure 5.1). Further we identify each used block as a sequence of marked and unmarked sub-blocks where a sub-block of block \(U_m\) is marked (referred to as \(U_m^j\), if it is the \(j^{th}\) marked sub-block of \(U_m\)) if it belongs to the sub-set \(S\) and if its priority is greater than that of task \(T_i\). unmarked otherwise.

Step 1.7: Compute the maximum possible scaling factor \(sf^i\): 

\[
sf^i = \max_{1 \leq m \leq k-1} sf_m
\]

where

\[
sf_m = \sum_{1 \leq j \leq m} \left( \frac{\left( \sum_{\forall l} U^j_l \right) + (U_{j+1,L} - U_{j,R})}{\sum_{1 \leq j \leq m, \forall l} U^j_l} \right)
\]

Step 2: \(sf = \text{Minimum (} sf^i \text{)} \ \forall i\)

Step 3: \(sf\) is the required maximal factor.

---

\(^4U_k\) is the used block of time that overlaps with the deadline \(d_i\). However, if the last block of used time, \(U_k\), does not overlap with the deadline \(d_i\), i.e., \(d_i < U_{k,L}\) then we set \(U_{k,L} = d_i\).
The fact that the above algorithm returns an maximal scaling factor is confirmed by the following proof:

5.4 Proof for the Presented Solution

Following are the observations about the Solution that would help us prove that the derived scaling factor is in fact maximal.

- There is no idle time in the interval \([U_{1,L}, U_{1,R}]\), because if there were any idle time then it would have been used by \(T_i\) resulting in \(T_i\) completing before the point \(U_{1,R}\).

- Blocks of execution \(U_i(i \geq 2)\) belong to only higher priority tasks. This is true because we have not taken any lower priority tasks into consideration here.

- The scaling factor we are trying to find for task \(T_i\) only guarantees that the task \(T_i\) will meet its deadline, by using the processor at times when its free (i.e., not executing any higher priority tasks). It is possible that the scaling factor derived can cause a higher priority task to miss its deadline. However, if a higher priority task does miss its deadline, it is not because of task \(T_i\) but due to its own execution time and the execution times of tasks higher than itself being scaled (this point is explained using an example later).

To see the effect of scaling the tasks by a factor, we look at the first scaling factor considered, namely \(sf_1 = \frac{\left(\sum v_i^{\prime}\left(U_{i,L}+U_{1,R}-U_{1,R}\right)\right)}{\left(\sum v_i^{\prime} U_i\right)}\) (refer to Figure 5.2).
Figure 5.2: Effect of Scaling by $s_{f_1}$

Since, this scaling does not affect the periods of tasks, if there were $I_j$ instances of a task $T_j (j \leq i)$ in the interval $(U_{1,L}, U_{2,L})$ before the scaling, there will still be the same number of instances and further they will arrive at the same points as before.

$$U_1 = U_{1,R} - U_{1,L} = \sum_{1 \leq j \leq i} I_j \times e_j \text{ where } I_i = 1$$

The processing requirement of task $T_j (\forall j \leq i)$, after scaling would become $e'_j = s_{f_1} \times e_j$, if $(j \in S)$, or $e'_j = e_j$, if $(j \not\in S)$. However, So long as the following condition holds true, task $T_i$ would complete by $U_{2,L}$:

$$\sum_{1 \leq j \leq i} (I_j \times e'_j) = U_{2,L}$$

We can confirm that this is in fact true:

$$\sum_{1 \leq j \leq i} (I_j \times e'_j) = \sum_{1 \leq j \leq i \& (j \in S)} (I_j \times s_{f_1} \times e_j) + \sum_{1 \leq j \leq i \& (j \not\in S)} (I_j \times e_j) = s_{f_1} \times \sum_{1 \leq j \leq i \& (j \in S)} (I_j \times e_j) + \sum_{1 \leq j \leq i \& (j \not\in S)} (I_j \times e_j)$$
While the above shows that the scaling factor is valid in the sense that it moves (forwards) the completion time of \( T_i \) to the point \( U_{2,L} \) (this argument can be extended to show that a factor \( s_{f,m} \) will forward the completion time of task \( T_i \) at most till \( U_{m+1,L} \)), it does not necessarily guarantee to be the maximal scaling factor. The maximal scaling factor is the largest such scaling factor among all \( s_{f,m} \) where \( 1 \leq m \leq k \). In order to see why this is so, observe that any factor \( s_{f,m} \) would result in the task \( T_i \) finishing before its deadline, therefore all \( s_{f,m} \) are valid, however, the one that is the largest (say \( s_{f,max} = s_{f,i} \)) is the desired result. To see why this is maximal, we note that any larger a factor would result in \( T_i \) finishing beyond \( U_{m+1,L} \) and any smaller would leave more room for scaling the tasks in question.

Observe that computation of scaling factor w.r.t task \( T_i \) only guarantees that \( T_i \) will meet its deadline honoring the processing requirements of all higher priority tasks. The scaling factor thus obtained does not guarantee against higher priority tasks missing their deadlines. If any higher priority task misses its deadline as a result of this scaling, then obviously, it would miss its deadline.
in spite of $T_i$ and therefore a prior scaling factor would prevail (an example below demonstrates this). In this way we compute the scaling factor $s_f^i$. We perform this computation for all values of $i$ from $h$ to $n$ and find the minimum of them, which is the desired final result.

5.5 Examples Demonstrating the Solution

The following examples demonstrate the various aspects of the technique. The first example involves three tasks, whose characteristics are given in Table 5.1 and the sub-set $S$ has only one task $\{T_2\}$.

Table 5.1: Example Task Table

<table>
<thead>
<tr>
<th>Task Id</th>
<th>Period</th>
<th>Exec Time</th>
<th>Deadline</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>100</td>
<td>40</td>
<td>100</td>
</tr>
<tr>
<td>2</td>
<td>150</td>
<td>40</td>
<td>150</td>
</tr>
<tr>
<td>3</td>
<td>350</td>
<td>35</td>
<td>280</td>
</tr>
</tbody>
</table>

Figure 5.3 gives a pictorial description of how the technique works on this example. The required maximal scaling factor is 1.5625. There are a few important points to note, that are not evident through this example. The next two examples are used to show these.

The second example demonstrates that, when computing the scaling factor w.r.t a given task $T_i$, it is not necessarily true that the last of the computed scaling factors, viz., $s_f^k$ is the maximum of all $s_f^m$. To see an example of this case, consider the following task-set:

The task-set $T$ has two tasks and the subset $S$ contains both of them. The computation of $s_f^2$ would be $\text{Max}(100/80 = 1.25, 145/120 = 1.20) = 1.25$. 
Figure 5.3: Operation of Task Set in Example 1

Figure 5.4: Operation of Task Set in Example 2
Table 5.2: Example 2

<table>
<thead>
<tr>
<th>Task Id</th>
<th>Period</th>
<th>Exec Time</th>
<th>Deadline</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>100</td>
<td>40</td>
<td>100</td>
</tr>
<tr>
<td>2</td>
<td>150</td>
<td>40</td>
<td>145</td>
</tr>
</tbody>
</table>

Note that the scaling factor $s_f^2$ is not determined by the second $s_f^2$ (last) computed scaling factor but by that factor which is the maximum. In this case the factor $s_f^1$. This same variation on the example also gives us a case for the point we made before, i.e., when computing the scaling factor w.r.t task $T_i$, the maximum of all the factors $s_f_m, 1 \leq m \leq k$ is to be taken. Clearly, if we were to take $s_f^2$ to be 1.20 (145/120) rather than 1.25 then there would still be some room for scaling.

In example 1, we see that the scaling factors are decreasing as we go from $i = 2$ ($s_f^2 = 1.75$) to task $i = 3$ ($s_f^3 = 1.5625$). This however, is not true in general. A simple variation on the example will show us why. Consider the task-set in Table 5.3 with $S = \{T_2\}$.

Table 5.3: Example 3

<table>
<thead>
<tr>
<th>Task Id</th>
<th>Period</th>
<th>Exec Time</th>
<th>Deadline</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>100</td>
<td>40</td>
<td>100</td>
</tr>
<tr>
<td>2</td>
<td>150</td>
<td>40</td>
<td>150</td>
</tr>
<tr>
<td>3</td>
<td>350</td>
<td>35</td>
<td>300</td>
</tr>
</tbody>
</table>

We now have $s_f^3 = Max(85/80, 145/80) = 1.8125$. Thus illustrating that the scaling factors don’t have to follow a decreasing trend as we add more tasks. This example also illustrates that the desired maximal scaling factor is the minimum $s_f^1$, i.e., 1.75 and not 1.8125.
Figure 5.5: Operation of Task Set in Example 3
Chapter 6

Schedulability of Task-Sets with Arrivals

The source of this problem as discussed in Chapter 4 stems from the first stage of solving the end-to-end schedulability problem. To recall, the problem of interest here is the schedulability of tasks which have end-to-end schedulability constraints, i.e., a task is a sequence of sub-tasks that execute on independent components. However, the task as a whole has an arrival time, period specification and a deadline requirement.

We showed in Chapter 4 that a solution to the problem of end-to-end schedulability (and subsequently scalability) requires that we are able to solve the single component schedulability of a set of tasks whose arrival times are non-zero. The reduction was facilitated by an important transformation, viz., phase adjustment. Phase adjustment is a technique that allows us to derive the parameters of arrival and periodicity of sub-tasks of a task. The principle behind the technique was briefly described in Chapter 4, a more detailed description follows

6.1 Phase Adjustment

Clearly, the parameters of arrival and periodicity of the first subtask of any task are known a priori (inherited from the task). However, subsequent sub-tasks
$T_{ij}$ ($j > 1$) of task $T_i$ are not necessarily periodic in nature. Therefore, their arrivals and their periodicities do not correspond directly to that of the tasks. We have to account for this unpredictability in timing behavior of sub-tasks following the first sub-task. The first sub-task $T_{i1}$ has the same periodicity as the original task $T_i$, therefore, it always arrives (or is ready to execute) at the start of the period $p_i$. However, the subsequent sub-task arrival times are dependent upon the completion time of the previous sub-task, i.e., if $T_{ij} \rightarrow T_{i,j+1}, j \geq 1$, then the arrival time of a particular instance $l$ of $T_{i,j+1}$ is dependent upon the completion time of the $l^{th}$ instance of sub-task $T_{ij}$. Further, the completion time of a sub-task instance is a function of its priority among the other ready tasks on the component. Therefore, we observe that there is a dependency between successive sub-tasks that has to be taken care of.

Phase adjustment is a mechanism that allows us to remove this dependence. Since $a_i$ is the arrival time or phase of task $T_i$, sub-task $T_{i1}$ inherits the phase of the task $T_i$, i.e., $a_{i1} = a_i$. The $l^{th}$ job instance of sub-task $T_{i1}$ arrives at $a_i + (l - 1)p_i$. Let the worst-case completion time (or response time) of sub-task $T_{i1}$ be $WC_{i1}$, i.e., any instance of $T_{i1}$ (call it the $l^{th}$) would complete no later than $a_{i1} + (l - 1)p_i + WC_{i1}$. We use the term $WC_{i1}$ to adjust the phase of the next sub-task $T_{i2}$. Therefore, the phase of $T_{i2}$, $a_{i2}$ is given by $a_{i1} + WC_{i1}$. This also guarantees that consecutive instances of subtask $T_{i2}$ will repeat periodically at an interval of $p_i$ time units.

This can be further generalized to find the phase $a_{i,j}$ of the sub-task $T_{ij}$ as $a_{i,j-1} + WC_{i,j-1}$. Also all sub-tasks of task $T_i$ are now guaranteed to directly inherit its period. We have the following a recurrence relation that captures the arrival time of a sub-task $T_{ij}$:
\[ a_{ij} = a_{i,j-1} + WC_{i,j-1} \]

In order to find a closed-form solution to this recurrence relation we have to know the base values, \( a_{i1} \) and \( WC_{i1} \). We already showed how to obtain \( a_{i1} \) from \( a_i \). The worst-case completion time \( WC_{i1} \) of sub-task \( T_{i1} \) can be obtained if we solve the problem of schedulability of tasks running on the component that \( T_{i1} \) runs. A solution to this problem is the subject of this chapter. Assuming for now that we do have a solution to this problem and hence are able to find the worst-case completion time of \( T_{i1} \), we complete the requirements to convert this to the following closed form:

\[ a_{ij} = a_i + \sum_{l=1}^{j-1} WC_{il} \]

Having obtained the value of \( WC_{i1} \) we can now use it to find the arrival time and hence the worst-case completion time of task \( T_{i2} \). Again, we are assuming that we know how to compute the worst-case completion times of subtasks running on a single component with non-zero arrivals. Note that the schedulability test for the end-to-end task \( T_i \) would now be a trivial comparison: if \( \sum_{1 \leq j \leq r} WC_{ij} \leq D_i \) then the task \( T_i \) is schedulable.

In the above discussion we have assumed that we have a mechanism that computes the worst-case completion times of subtasks given their arrival times, periodicities and priorities. This is the subject of the following discussion.
6.2 Problem Statement and Solution

We recall from Chapter 4, the formal statement of the problem (Problem 4.2.2) of interest to us here:

*Given a task-set T of n tasks executing on a single component, find the worst-case completion times of all tasks in the task-set.*

The solution to this problem is based on the following observations:

1. Is there a period $L$ for the task-set such that, looking at the behavior of a task $T_i$ during the interval $a_i$ and $L$ is sufficient to determine the worst-case response time of the task $T_i$? Note that, if $a_i = 0, \forall i$, then $L$ is given by the LCM of the task periods. The worst-case response time of a task $T_i$ is the maximum response time of all instances of $T_i$ in this interval.

2. For arbitrary arrival phasings of tasks, the repetition of the initial phasing pattern\(^1\) occurs at a point $L$ units later (where $L$ is given by the LCM of the periods). The state of the scheduler (defined later) is not the same at these two points. Therefore, repetition of phasing pattern does not necessarily guarantee that the task-set behavior will repeat itself.

3. If the task arrival times are *inverse monotonically increasing* with the priority, i.e., the highest priority task is the earliest to arrive ($a_i < a_j$ if $i < j$), then the repetition of the phasing pattern is an indication that the task-set would repeat its behavior.

---

\(^1\)The phasing pattern is the relative arrivals of the various tasks under consideration.
4. Given an arbitrary task phasing \( a \), we can derive an alternate phasing \( a' \) which has the characteristic that the arrival times monotonically increase with the priority. Further, this phasing can be used to determine the worst-case response time of the tasks in task-set.

The following theorem is the basis for the approach.

**Theorem 6.2.1**: Given that the arrival times of tasks in a task-set are inverse monotonic with priority (\( a_i \leq a_j \) if priority of \( T_i \) is greater than priority of \( T_j \), i.e., \( j > i \)), the worst-case response time instance of a task \( T_i \) belongs to the interval \([a_i, a_i + LCM(T_1, \ldots, T_i)]\).

**Proof.** For task, \( T_i \), the only tasks that it would have to compete with, are the higher priority tasks \( T_1, T_2, \ldots, T_i \). We are therefore interested in finding that point in time at which, the phasing of task \( T_i \) (given by \( a_i + x_i \times p_i \), for the \( x_i \)th instance) with respect to other higher priority tasks is same as that at time \( a_i \). Further, this point must be such that the state of the scheduler must be same as it was at \( a_i \).

The relative phasing of task \( T_i \) with respect to the task \( T_1 \) can be captured as: Task \( T_i \) comes \( a_i - a_1 \) units of time after task \( T_1 \). Assuming the existence of a point where this phasing repeats, and further that there are \( x_1 \) and \( x_i \) instances respectively of \( T_1 \) and \( T_i \) before this point, we have the following condition:

\[
(a_i + x_i \times p_i) - (a_1 + x_1 \times p_1) = a_i - a_1
\]

\[
\Rightarrow x_1 \times p_1 = x_i \times p_i
\]
We can derive similar conditions for task $T_i$ w.r.t other tasks. The resultant condition is:

$$x_1 \times p_1 = x_2 \times p_2 = \ldots = x_i \times p_i = L$$

where $a_i + L$ is the desired point. Clearly the $LCM$ of $p_i$ is solution for the above equation if we assume integral values of $p_i$.

![Figure 6.1: A task-set's execution between the start and $L$](image)

Next, we have to show that the state of the scheduler with respect to the task $T_i$ is the same at both points $a_i$ and $a_i + L$. We use the method of mathematical induction to show this.

**Definition 6.2.1**: The state of the scheduler w.r.t task $T_i$ at the time of arrival of the $k$'th instance of task $T_i$ is given by $S^k_i = \{S^k_{1,i}, \ldots, S^k_{i-1,i}, S^k_i\}$. The term $S^k_{j,i}$ is the amount of time that the task $T_j$ executed for, before the point $a_i + (k - 1) \times p_i$ and since its first invocation (taken modulo its period).
Note that, since the state of the lower priority tasks $T_j, j > i$ do not affect the schedulability of the task $T_i$, they don't figure in the system state with respect to task $T_i$. Also note that, we are concerned only with the state of scheduler at points that are arrival times of tasks because we seek to show that the state at these points repeats. Further, $S_{i,i}^k = 0$, because, the last invocation of task $T_i$, viz., $k - 1$'th should have completed before the arrival of the $k$'th instance (otherwise we would have declared that the task missed its deadline and that's the end of it).

**Basis:** Consider the point $a_i + L$ where we have already shown that the phasing of the task $T_i$ is the same as it was at $a_i$. The highest priority task, $T_1$ has an arrival at $a_1 + x_1 \times p_1$ and acquires the processor (being the highest priority ready task). The duration of time between this completion and the arrival of the task, $T_2$ at $a_2 + x_2 \times p_2$ (refer to Figure 6.1), can be used by any of the tasks $T_j (2 \leq j \leq i)$. Note that this same duration at the beginning, i.e., when the first instance of $T_1$ completes and the first instance of $T_2$ is ready was necessarily idle. However, the state of the processor with respect to task $T_2$ at the point $a_2 + x_2 \times p_2$ is exactly the same as at the point $a_2$, because, the lower priority tasks would not affect the completion times of the instances of task $T_1$ and further the latest instance of task $T_2$ would have completed. Therefore, the state of the scheduler w.r.t task $T_2$ at the point $a_2 + x_2 \times p_2$ is same as it was at $a_2$, viz., $\{S_{1,2}^1, S_{2,2}^1\}$.

**Inductive Hypothesis:** Let us assume that the result holds for the $i - 1$'th task, i.e., the state of the scheduler w.r.t. task $T_{i-1}$ at $a_{i-1} + x_{i-1} \times p_{i-1}$, viz., $\{S_{1,i-1}^{x_{i-1}}, \ldots, S_{i-2,i-1}^{x_{i-1}}, S_{i-1,i-1}^{x_{i-1}}\}$ as it was at $a_{i-1}$, viz., $\{S_{1,i-1}^1, \ldots, S_{i-2,i-1}^1, S_{i-1, i-1}^1\}$. Note that between the points $a_{i-1} + x_{i-1} \times p_{i-1}$ and $a_i + x_i \times p_i$, the number
of tasks of priority higher than task $T_i$ that would arrive are the same as in the interval $a_{i-1}$ and $a_i$. Further, since the task $T_i$ has to complete before its deadline (which is less than its period; If it does not then we just report so and that's the end of it), each of the higher priority tasks would have gotten the same amount of execution time in these two intervals, implying that:

$$S_{j,i}^* - S_{j,i-1}^* = S_{j,i}^1 - S_{j,i-1}^1 \forall j \leq i - 1$$

Note that, when $j = i - 1$, the terms $S_{i-1,i-1}^* - S_{i-1,i-1}^1$ are both 0. Now, since the result we are trying to prove, holds for the task $T_i$, we have:

$$S_{j,i-1}^* = S_{j,i-1}^1 \forall j \leq i - 1$$

Therefore,

$$S_{j,i}^* = S_{j,i}^1 \forall j \leq i$$

Which implies that the state of the scheduler at the point $a_i + x_i \times p_i$ is the same as that at $a_i$. Therefore, the result holds for the task $T_i$. $\square$

Having shown that both, the phasing repeats after $L$ units of time and also that the state of the scheduler is same when this repetition occurs, the result follows. $\square$

In deriving the result in theorem 6.2.1 we have assumed that the arrival times of tasks are such that the highest priority task is the earliest to arrive and the arrival times increase with priority. However, in reality, this assumption restricts the practicality of the result. In the following, we describe a mechanism by which we can get rid of this assumption without hurting the result.

---

2The last term when $j = i$ has been conveniently added because $S_{i-1,i-1}^* - S_{i-1,i-1}^1 = 0$. 

---
Given an arbitrary arrival phasing of tasks the following algorithm converts it into an alternate phasing where the arrival times increase with the priorities.

2 Algorithm Arb_to_Incr

Parameters: \( a_1, a_2, \ldots, a_n \), and \( p_1, p_2, \ldots, p_n \) the arrival times and periodicities of tasks \( T_1, T_2, \ldots, T_n \) respectively.

Result: \( a'_1, a'_2, \ldots, a'_n \),

Initialize: \( a' = a \);

The first task arrival is unchanged.

for \((i = 2 \text{ to } n)\) do

If \((a_i < a'_{i-1})\)

\[ y = 1; \quad \text{while } (a_i + y \times p_i < a'_{i-1}) \]

\[ y \leftarrow y + 1; \]

end

\[ a'_i \leftarrow a_i + y \times p_i; \]

end

end

We take an example to demonstrate the operation of the above algorithm. Consider a task-set with four tasks \((T_1, T_2, T_3, T_4)\), with the following values for arrival times and periodicities: \((a_1 = 5, a_2 = 3, a_3 = 4, a_4 = 0)\), \((p_1 = 10, p_2 = 10, p_3 = 16, p_4 = 12)\). The first task's arrival time remains unchanged, however since the task \( T_2 \)'s arrival is before \( T_1 \)'s, its new arrival time.
Figure 6.2: A task-set's execution between the start and $L$

$a'_2$, is computed to be $a_2 + p_2$ which is 13. Now task $T_3$'s arrival time $a_3 = 4$ is less than $a'_2 = 13$, therefore its new arrival time $a'_3$ is $a_3 + p_3$ which is 20. Task $T_4$ arrives at $a_4 = 0$ which is less than $a'_3 = 20$, therefore its new arrival time $a'_4$ is $a_4 + 2 \times p_4$ which is 24. Now the new arrival times of the tasks in the task-set are $(a'_1 = 5, a'_2 = 13, a'_3 = 20, a'_4 = 24)$.

Before we discuss the mechanism in detail, it is important to ascertain the relationship between the original arrival phasing and the modified arrival phasing. Since, the modified arrival pattern guarantees the repetition of the task-set behavior, in order to find the worst-case response time of any task, we only have to look for its instances between its original arrival time and the point at which the new phasing repeats itself.

The algorithm for the complete mechanism follows:

3 Algorithm
Parameters: \(a_1, a_2, \ldots, a_n\), and \(p_1, p_2, \ldots, p_n\) the arrival times and periodicities of tasks \(T_1, T_2, \ldots, T_n\) respectively.

- Find the modified arrival times, \(a'\), for tasks by invoking the procedure Arb_to_Incr.
- Repeat for each task \(T_i\) in turn:
  
  * Determine if the task meets all its deadlines assuming a worst-case phasing (i.e., ignoring arrivals). If it does not then, report so and QUIT.
  
  * Find the completion time of all task instances of \(T_i\) occurring during the interval \(a_i\) and \(a_i' + LCM\{T_j, j \leq i\}\).
  
  * Find the maximum and report it as the worst-case response time of the task \(T_i\).

end

6.3 Example Demonstrating the Solution

Consider the task-set in Table 6.1 below.

The computation of the response times of tasks in this task-set using the mechanism described above is given in Figure 6.3. In the Table 6.1, the last
two columns give respectively the worst-case response times of the tasks using the critical instant assumption and our approach. It is clear that the critical instant assumption has resulted in the computation of a higher response time in the case of the last three tasks. In order to best appreciate the merit of finding the worst-case completion time of a task using the precise test described in this chapter as opposed to using the critical instant assumption, we introduce a couple of new measures of comparison, viz., apparent slack and slack savings.

Note that though both these worst-case response times are still within the deadline bound, there is a difference in the apparent slack of tasks. We define the apparent slack of a task\(^3\) to be the difference between the deadline of a task and its worst-case completion time. Note that a positive apparent slack for a task guarantees its meeting its deadline. However, a larger apparent slack signifies that a task is more capable with regards to, accommodating task interdependence (eg., precedence), withstanding temporary overloads, accommodating aperiodics in the system, restricting jitter in end-to-end systems.

We define a measure called the slack savings, \(ss\), for a task \(T_i\) as the ratio of the gain in the apparent slack per unit real slack:

\[
ss_i = \frac{WC_i^c - WC_i^r}{d_i - c_i}
\]

Note that in the above example we have chosen the deadlines of tasks to be equal to their periods. However, in general the deadlines can be less than or greater than the periods. Also note that the example shows that the arrival times are monotonic with priority, however, this need not be the case in general.

\(^3\)as opposed to the original slack of the task which is independent of other tasks it has to compete with and is defined to be the difference between the deadline and the execution time of the task
In the above example we achieve the following slack savings: $ss_1 = 0\%$, $ss_2 = 10\%$, $ss_3 = 23\%$, $ss_4 = 25\%$.

### 6.4 Discussion of the Result

The reader will observe that the above treatment of the end-to-end schedulability problem assumes that all tasks access the components in the same order. This scenario is similar to the classical periodic flow shop model [4]. However, as will become clear in the following discussion, this assumption can be relaxed.

We consider the following scenarios for the order in which the tasks use the various components:

- **Case 1: Periodic flow shops** [15, 4]: All tasks execute on the same components in the same order. Every task $T_i$ has exactly $r$ (the number of components) sub-tasks, $T_{i1} \rightarrow T_{i2} \rightarrow \ldots \rightarrow T_{ir}$, where each sub-task $T_{ij}$ executes on component $j$. This case is a special instance of the next case, however, we treat it separately because of its practical significance.

- **Case 2**: The use of components by the tasks are ordered but the tasks
Figure 6.4: End-to-End scenarios
don't necessarily access the same resources: We assume that any two tasks $T_i, T_j$ that have subtasks that run on two components $R_k, R_l$, do so in the same order in both tasks. Further, the component used by a sub-task $T_{ij}$ is not used by any other sub-task of $T_i$.

- **Case 3: Arbitrary order flow shops:** The order in which the components are used by a task can be arbitrary (as opposed to ordered access in Case 2). There are two possibilities under this case, one which disallows components from being reused and the second where components are allowed to be reused.

### 6.4.1 Periodic flow shops

If we assume an ordering of the $r$ components in use to be in numerical order then the function $Res(T_{ij})$ can be taken to be equal to $j$ (i.e., the $j^{th}$ component). Therefore we now have $n$ tasks with each task consisting of $r$ subtasks where the $j^{th}$ subtask of every task $T_i$ ($\forall i$) runs on component number $j$.

In order to determine the schedulability of the task-set we have to study the schedulability of each task in turn. Phase adjustment guarantees that sub-tasks of a task inherit its periodicity and further they are independent of each other. Therefore the schedulability test for a task $T_i$ is given by:

$$a_i + \sum_{j=1}^{r} WC_{ij} \leq D_i$$

Where, $WC_{ij}$ is the worst-case completion time of the subtask $T_{ij}$. In order to find the worst-case completion of the subtask $T_{ij}$ which runs on the component $j$ we have to consider all the subtasks that run on the component
Starting from $j = 1$, we see that for the first component we know the arrival times, periods and priorities (note that the subtask priority can be explicitly given or the subtask can inherit the original task's priority) of all subtasks that run on it. That is, for a given subtask $T_{i1}$, its arrival time is $a_i$ and its period is $p_i$. We can find its worst-case completion time by the mechanism described in the previous section. Let $WC_{i1}$ be the worst-case completion time thus determined (Note that this worst-case completion time is the time taken by the subtask to complete after its arrival).

We now fix the arrival time of the second subtask of $T_i$ (i.e., $T_{i2}$) as $a_i + WC_{i1}$. This fixing of the arrival is a result of the phase adjustment mechanism described before. Further it ensures that the second subtask will be periodic with period, $p_i$. We now know all the parameters (viz., arrival phasing, period and priority) we need to determine the worst-case completion time of the second subtasks of all the tasks. Knowing the value of $WC_{i2}$ ($\forall i$) we are able to find the timing parameters of the third subtasks and so on.

### 6.4.2 Ordered Access

This a more general case than the periodic flow shop case in that tasks don't necessarily access all the components. However, when they do access a particular component its relative order with respect to other components is honored in all tasks. We once again assume that the components are numbered in order. We do the following modification to the formal specification of this case:

We assume that each task $T_i$ is a sequence of subtasks $T_{i1} \rightarrow T_{i2} \rightarrow \ldots \rightarrow T_{ir}$. However, if the task $T_i$ does not have a subtask running on component $j$ then the corresponding subtask $T_{ij}$ has an execution time, $e_{ij} = 0$. 

By specifying the model in this way we are able to treat this case similar to the previous case. However, note that for all subtasks that have a zero execution time their worst-case completion times are also zero.

6.4.3 Arbitrary order with no revisit

The major problem with this ordering scenario is that it is not always possible to find the timing parameters of all subtasks that run on a particular component. For example in Figure 6.4 we see that task $T_1$ uses the components in the order $R2 \rightarrow R4 \rightarrow R1$, task $T_2$ uses components $R1 \rightarrow R3 \rightarrow R2 \rightarrow R4$ and task $T_3$ uses components $R2 \rightarrow R3 \rightarrow R1$. Determining the parameters (mainly arrival times) of subtasks that run on component $R1$, $T_{1,1}, T_{2,1}, T_{3,1}$ involves finding the worst-case completion times of subtasks $T_{1,1}, T_{1,2}, T_{3,1} and T_{3,2}$. It can be seen that this is not possible without addressing the schedulability on the components $R2, R3 and R4$.

An alternative approach to this case would be to ignore the arrival information of tasks (and subtasks). Note however that the penalty of ignoring arrival information is that we end up doing a pessimistic schedulability analysis.
Chapter 7

Scalability in End-to-End Systems

As shown in Chapter 4, the problem of scalability of tasks in end-to-end systems manifest itself in two forms, viz., (i) Changes to components and, (ii) Changes to Tasks. We have also shown that solving this problem in either of these two flavors reduces to solving the following two problems 4.2.4 and 4.2.5.

4.2.4: Given a task-set $T$ of $n$ tasks (with non-zero arrival times) executing on a single component, find the worst-case completion times of all tasks in the task-set.

4.2.5: Given a schedulable task-set $T$ of $n$ tasks executing on a single component and a subset $S$ of $T$, find the maximum scaling factor $sf$ with which all tasks in $S$ can be scaled without violating the schedulability of any of the tasks in $T$.

The first of the two problems was the subject of the previous chapter. This chapter is devoted to presenting a solution to the second. As shown in the previous Chapter 4, the problem of schedulability in end-to-end systems can be reduced to a series of single component schedulability problems. However, the single component schedulability problem has to accommodate task arrival times. Similarly, the problem of scalability in end-to-end systems can
be reduced to a series of single component scalability problems provided we accommodate task arrival information into the computation. Further, to find the scalability of a sub-task we have to know its deadline and also the deadlines of all other sub-tasks involved in its analysis. There is no straightforward way to derive the sub-task deadlines.

A major research issue in end-to-end scheduling has been the derivation of sub-task deadlines. Given an end-to-end task's deadline the problem of finding an optimal\(^1\) division of this deadline among the sub-tasks is intractable [15] (NP-complete [12]). This result has prompted a heuristic approach [4, 15], two such heuristics being: (i) divide the task's slack\(^2\) equally among the sub-tasks; (ii) divide the task's slack among its sub-tasks in a weighted proportion of their execution times;

The above two heuristics vary mainly in their sensitivity to the execution times of tasks. For example, the second heuristic is built on the assumption that the shorter a task's execution time requirement, the more likely it will have its requirement met and therefore the lower is the slack assigned to it. The first heuristic is built on the assumption that the priority inherited by a sub-task has a greater impact on its ability to meet its execution time requirement than its execution time itself. Thus the slack is divided equally among all sub-tasks. This allows us to reduce the end-to-end scalability problem to \(m\) single component scalability problems.

---

\(^1\)In the sense that, if there exists a division that would help the task meet its deadline then the mechanism should find it.

\(^2\)The slack of a task is given by the difference between its deadline and its execution time.
In our research, we have chosen the second heuristic because it is more general of the two. The intuition behind the heuristic is to divide the slack of the task proportionally among its sub-tasks. We can find the total slack of the task $T_i$ as $sl_i = d_i - \sum_{v_j} e_{ij}$. We divide this among the sub-tasks in the ratio of their execution times, $e_{ij}$. Therefore,

$$d_{ij} = e_{ij} + \frac{e_{ij}}{\sum_{v_j} e_{ij}} \times sl_i$$

The following section describes a mechanism for finding the scaling factor that incorporates the arrivals of tasks. We also give an informal proof for its correctness. In order to simplify the presentation we assume that the scaling factor we desire is a common scaling factor for all tasks in the task-set. Note that the case of general scaling (sub-set scaling) can be easily derived on the same lines.

### 7.1 Problem Statement and Solution

As we did when we dealt with the problem of schedulability using arbitrary task arrivals in the previous chapter, we assume that the arrival times of task are in increasing order of their priorities. Therefore, the highest priority task $T_1$ is the first to arrive (time $t = 0$) and $T_i$ arrives prior to $T_j$ if $i < j$.

The procedure for finding the common scaling factor of a task set, proceeds on the same lines as that for arrival times being all equal to 0. We find the scaling factor $sf^i$, with respect to each task $i$ ($1 \leq i \leq N$) and take the minimum as the required result. Any scaling factor $sf^i$ has the following sense: This is the maximum factor by which all task execution times can be
scaled such that the task $T_i$ will meet its deadline while continuing to honor all higher priority task requirements (not necessarily their deadlines). However, the difference comes in the fact that when we are finding the scaling factor with respect to a particular task $T_i$, we no longer can settle by considering only one instance (the worst-case instance, which is the first instance using the critical instant argument) but we have to consider all instances of this task between the points $a_i$ and $a_i + L$ (refer Chapter 6).

Following are some of the distinguishing characteristics of the problem when compared to the treatment in Chapter 5.

- It would seem that it is sufficient to consider the worst-case execution instance (of a task $T_i$) and apply the same technique as before (as in Chapter 4) to find the scaling factor. However, this is not true for the following reason: the scaling factor is determined by both the completion and the idle time left before the deadline; the worst case-completion of a task instance does not necessarily guarantee that the idle time left between its completion and its deadline after accommodating higher priority tasks is a minimum.

- The critical instant assumption, in addition to restricting our consideration to a single instance, has also allowed us to conveniently ignore any higher priority tasks that would arrive prior to task $T_i$'s arrival. The possibility of the following scenario (refer to Figure 7.1) has to be taken into account for arbitrary arrivals: In computing the scaling factor for the first instance of task $T_i$, we cannot ignore the blocks of execution that precede the point $a_i$ (i.e., $U_1, U_2, \ldots, U_{q-1}$). This is so because, it is likely that a
factor computed ignoring these could cause the used blocks of execution before \( a_i \) to be scaled in such a way that the begin time of tasks in the block that \( a_i \) belongs to, could be affected by tasks other than the ones within. This results in the computed factor being invalid.

![Figure 7.1: Execution Profile Task \( T_i \)'s First Instance](image)

We now discuss the mechanism along with an explanation of why the mechanism works. We are interested in computing the scaling factor \( sf_i \), with respect to a particular task \( T_i \). We once again note that this factor does not guarantee that all higher priority tasks would meet their deadlines, it only ensures that the task \( T_i \) will meet its deadline in spite of honoring the requirements of higher priority tasks.

Let us consider the first task instance of task \( T_i \). Assume that there is only one block of execution before the arrival of task \( T_i \) at \( a_i \) and there are a number of blocks after the completion and before the deadline (refer to Figure 7.2). We are interested in stretching the deadline as far as possible while honoring the requirements of higher priority tasks. The only way this can be accomplished is by stretching the completion a step at a time with each step attempting to consume the next available idle time (Refer to Chapter 5 for reasoning). The required result (the scaling factor with respect to this instance
of task $T_i$) would then be obtained by taking the maximum (because all these factors are valid and we are interested in finding the optimal one) among such computed factors.

![Figure 7.2: Figure 7.1 assuming $q = 2$](image)

We now look at how we can stretch the completion time to achieve the motive described above. Since we assumed that there is only one block of execution (obviously comprises of at least one instance of every higher priority task), following are the points to note while trying to stretch the completion time of the first instance of the task $T_i$ to consume the first slot of idle time:

- If we ignore the block of execution before the arrival of task $T_i$ then the scaling factor would be $f = \frac{U_{3.L} - U_{2.L}}{U_2}$. However, it is possible that this factor could result in the ignored block (i.e., $U_1$) being scaled beyond the point $U_{2.L}$ (we call this the unfavorable event for this choice of scaling factor, NFE1), thus invalidating the factor. On the contrary, in the event that this scaling factor does not scale $U_1$ beyond the point $U_{2.L}$ (we call this the favorable event for this choice of scaling factor, FE1), this factor is clearly valid and effective in stretching the task completion time till $U_{3.L}$. 
• If instead, we use the scaling factor to be \( f' = \frac{U_2 - U_3}{U_2 + U_1} \), it is possible that the resultant factor does not scale \( U_1 \) to occupy the whole of the idle time between \( (U_1, R, U_2), \) resulting in \( U_2 \) being stretched beyond \( U_3, L \) and consequently the completion time being stretched beyond \( U_3, L \) (we call this the unfavorable event for this choice of scaling factor \( \text{NFE}_2 \)). Note that this possibility has come up because the task \( T_i \) is not ready to use the idle time between \( (U_1, R, U_2) \). On the contrary, in the event that this factor causes \( U_1 \) to be scaled beyond the point \( U_2, L \) (we call this the favorable event for this choice of scaling factor, \( \text{FE}_2 \)) then clearly the completion time of task \( T_i \) will be within \( U_3, L \) (in fact it will be exactly \( U_3, L \)).

We note that there are two possibilities (or events) in favor of each of the above choices and two that are not in favor. However, we will show that the true answer lies in finding the minimum of these two possible factors. That is, picking the minimum of these two factors as the solution leads us to realize that the unfavorable possibility is actually not possible. An explanation follows:

We have two possibilities to consider:

• \( f < f' \): The favorable event (\( \text{FE}_1 \)) corresponding to this choice of the factor is valid in giving us the desired result. However, we have to show that unfavorable event, \( \text{NFE}_1 \) will not occur. We show this by contradiction:

Let us say \( U_1 \) gets scaled beyond the point \( U_2, L \) (i.e., the event \( \text{NFE}_1 \) does occur). \( f' \), being the larger of the two, using it as the scaling factor would scale \( U_1 \) beyond \( U_2, L \) too. But, since \( f' \) has been derived to stretch both
$U_1$ and $U_2$ over $(0, U_{3, L})$, if it does stretch $U_1$ into the start of $U_2$, then there would be no idle time between the points $(0, U_{3, L})$. This implies that $f' < f$ because, the bumped time$^3$, say $\delta = f' \times U_1 - U_{2, L}$ and the scaled $U_2 = f' \times U_2 - U_2$ together fitted within the interval between $(U_{2, R}, U_{3, L})$, whereas $f$ scaled only $U_2$ to occupy the same interval. The conclusion that, $f' < f$ contradicts our assumption that $f$ is the smaller of the two factors. Hence the result.

- $f > f'$: The favorable event (FE2) corresponding to this choice of the factor is valid in giving us the desired result. However, we have to show that unfavorable event, NFE2 will not occur. We show this by contradiction:

   Let's say $U_1$ does not get scaled beyond the point $U_{2, L}$ when scaled by $f'$ (i.e., the event NFE2 does occur). Since, $f > f'$, $U_2$ does not go beyond $U_{3, L}$ when scaled by $f'$. However, the very definition of NFE2 says that $f$ stretches $U2$ beyond $U_{3, L}$. This is a contradiction. Hence the result.

Observe that the favorable events in both choices of scaling factors achieve the following: The completion time of the task $T_i$ is stretched to the point $U_{3, L}$. We now extend this to the case that the number of blocks of execution prior to the arrival of the first instance task $T_i$ is more than one. In fact, we wish to extend this argument to the case that there are $q - 1$ blocks of execution before the arrival of the first instance of $T_i$. The generalization is straightforward. If there is more than one block of execution then the scenario would be as in Figure 7.1. The scaling factor associated with stretching the

---

$^3$the excess scaled time that was carried from scaling $U_1$ beyond the point $U_{2, L}$
completion time of the first instance of task $T_i$ to consume the first idle interval beyond its completion would be given by:

$$F_q = \min \left( \frac{U_{q+1,L} - U_{1,L}}{U_r}, \frac{U_{q+1,L} - U_{2,L}}{U_r}, \ldots, \frac{U_{q+1,L} - U_{q,L}}{U_r} \right)$$

Where $q$ is the index of the block that contains the arrival of the first instance of $T_i$ (from the fact that there are $q - 1$ blocks of execution before its arrival). Note that this is also the index of the block that contains the completion of $T_i$, because, there cannot be any (processor) idle time between a task's arrival and its completion. We represent this factor by $F_q$ to signify that this is the factor with which all $T_j$ ($j \leq i$) must be scaled to fill the first idle interval after the completion (known to overlap with the block $U_q$) of this instance (the first that is) of task $T_i$. The subscript $q$ here is only to identify the block which overlaps with the completion of this instance of $T_i$. The representation will become clear when we proceed to the next stage of derivation, i.e., the scaling factor for an arbitrary instance of $T_i$ (not just the first that is).

Now consider the point corresponding to the deadline of this instance of $T_i$, $a_i + d_i$. Our aim is to try to extend the completion of this instance at most till this point. Clearly, if this point overlaps with a used block (call it $U_{k+1,L}$), then we cannot possibly extend $T_i$'s completion beyond the start of this interval. This is obvious from the fact that the overlapped block in question contains executions of higher priority tasks that cannot be preempted by $T_i$. On the other hand if the point in question does not overlap with any used block then we can consider filling only part of the idle interval that contains this point, viz., the idle interval between the right end of the used-block preceding
the deadline point and the deadline point itself. In this second case, we set $U_{k+1,L} = a_i + d_i = U_{k+1,R}$, i.e., we create a zero sized used block that overlaps with the deadline. Here $k$ is the index of the used-block that precedes the deadline.

Therefore, if we assume that there are $k - q$ such idle intervals beyond $U_q$ and before the deadline of this instance at $d_i$ then we have to find $k - q$ such scaling factors $F_m$ (that is $q \leq m \leq k$). Accordingly, $k$ is the index of the used-block that precedes the deadline point $a_i + d_i$. Now, the general formula for $F_m$ is given by:

$$F_m = \min \left( \frac{U_{m+1,L} - U_{i,L}}{\sum_{r=1}^{m} U_r}, \frac{U_{m+1,L} - U_{2,L}}{\sum_{r=2}^{m} U_r}, \ldots, \frac{U_{m+1,L} - U_{q,L}}{\sum_{r=q}^{m} U_r} \right)$$

The scaling factor for the first-instance of $T_i$ is the maximum among all computed factors for accommodating the next idle interval. Clearly, each of these factors is a valid factor in the sense that it does not extend the completion time of the first instance beyond its deadline. Therefore, the required factor is the maximum among such valid factors given by:

$$s_{f_1} = \max_{q \leq m \leq k} F_m$$

We now have to generalize the above formula for any arbitrary instance of $T_i$ (say the $l$'th). Clearly there are $x_i$ (refer to Chapter 6 instances of $T_i$) that have to be considered. Therefore, $l$ ranges from 1 to $x_i$. If we find the scaling factors $s_{f_i}^{l}$ for each of the $x_i$ instances of $T_i$ then we can obtain the scaling factor $s_{f_i}$ as the minimum among all these. This is clear from the fact that picking a factor larger than the minimum results in at least one of the instances missing its deadline. So, we have:
Before, we find the general scaling factor $s f^i$ of an arbitrary instance of $T_i$, it is important to notice some important considerations in dealing with the second instance (which will easily extend to arbitrary instances). The second instance of $T_i$ is ready at time $a_i + p_i$. Its ability to start (i.e., get the processor) is affected by higher priority tasks arriving beyond the point $a_i + p_i$ and, also those tasks executing between the deadline of its previous instance at $a_i + d_i$ and the point $a_i + p_i$. Note that, we have already taken care of tasks arriving before the point $a_i + d_i$ in finding the scaling factor of the first instance. Therefore, the point $a_i + d_i$ for task $T_i$'s second instance is equivalent to the point $a_1$ (assuming that the task arrivals are in increasing order; further this point can be taken to be $t = 0$). In finding the scaling factor for this instance, we have to consider used-blocks from that which overlaps $a_i + d_i$ (if this is a zero-sized block then consider the next block), to the block that contains the arrival $a_i + p_i$ on one side. On the other side, we have to consider used-blocks between the block that contains $a_i + p_i$ to the block that contains the deadline of this instance at $a_i + p_i + d_i$ (remember that if there is no such block that overlaps with the deadline then we create a zero-sized used-block to overlap it).

Now in the general case, that is, when we wish to find the scaling factor for an arbitrary instance $l$ we define the following notation (refer to Figure 7.3):

- $v$: $U_v$ is the used-block that contains the deadline of the $(l-1)$'th instance of $T_i$. If however, $U_v$ is a zero-sized block then $v$ is the index of the next
block following the deadline of the \((l-1)\)'th instance at \(a_i+(l-1) \times p_i + d_i\).

As a special case, for the first instance \(v = 1\).

- \(q\): Is the block that overlaps with the arrival of the \(l\)'th instance of task \(T_i\).

This is also the block that contains the completion of the \(l\)'th instance.

- \(k\): \(U_{k+1}\) is the block that contains the deadline of the \(l\)'th instance at \(a_i+(l-1) \times p_i + d_i\). Note that, if the deadline does not overlap with a used block then we create a zero-sized used-block at \(a_i+(l-1) \times p_i + d_i\). \(k\) is then given by the used-block that precedes this newly created zero-sized block.

The formula for the scaling factor of an arbitrary instance (say \(l\)) of \(T_i\) (represented as \(s_{fl}\)) is now given by:

\[
s_{fl} = \max_{q \leq m \leq k} F_m
\]

where \(F_m\) is given by:

\[
F_m = \min \left( \sum_{r=v}^{m} \frac{U_{r+1,L} - U_{v,L}}{U_r}, \sum_{r=v+1}^{m} \frac{U_{r,L} - U_{v+1,L}}{U_r}, \ldots, \sum_{r=q}^{m} \frac{U_{r,L} - U_{q,L}}{U_r} \right)
\]

We now have the scaling factor \((s_{fl})\) with respect to a task \(T_i\). In order to find the final common scaling factor \(sf\) we follow the same lines as in Chapter 5. Therefore, the required scaling factor \(sf\) is given by:

\[
sf = \min_{1 \leq i \leq n} sf^i
\]

The complete algorithm to find the scaling factor for task \(T_i\) follows:

4 Algorithm Scale_Factor\((T_i)\)
Figure 7.3: Execution Profile of the \( l \)th instance of \( T \).

Variables:

\( l = 0 \): task instance

\( sf^i \): the scaling factor for task \( i \) instance \( l \).

Step 0: Initialization. \( sf^i = \infty \)

Step 1: For each task instance \( l \) of \( T \), between \( a_i \) and \( a_i + L \) Repeat

Step 1.1: Find the completion time for the job \( l = compl_i \);

Step 1.2:

Fit equal and higher priority task instances that would arrive between the points \( G \) and \( a_i + (l + 1) \times d_i \). The point \( G \) is \( a_i \) for the first instance, \( l = 1 \) and for subsequent instances, \( l > 1 \) it is given by the deadline of the previous instance, \( a_i + l \times d_i \).

The scheduling points are, \( U_{1,L}, U_{2,L}, \ldots, U_{k,L} \), where, \( U_m = U_{m,R} - U_{m,L} \) denotes the \( m \)th used time block (refer to Figure 7.1).

The used interval among these blocks which overlaps with \( a_i + l \times P_i \) is \( q \) (note that this is also the block that contains \( compl_i \), because there can be no idle time between the instances arrival and it completion).

Step 1.3:
Compute the scaling factor $sf^i$ for job $i$:

$$Max_{q \leq m \leq k} F_m$$

where:

$$F_m = \min \left( \frac{U_{m+1,L} - U_{1,L}}{\sum_{r=1}^{m} U_r}, \frac{U_{m+1,L} - U_{2,L}}{\sum_{r=2}^{m} U_r}, \ldots, \frac{U_{m+1,L} - U_{m,L}}{U_m} \right)$$

**Step 1.4:** if $(sf^i < sf^j)$ then $sf^i = sf^j$.

**Step 2:** $sf^i$ is the desired scaling factor for task $T_i$.

Having obtained the scaling factor $sf^i$ for each $i$ in turn we can now determine the optimal scaling factor, $sf$ for the task set, which is the minimum of $sf^i, \forall i$.

### 7.2 Example Demonstrating the Solution

To demonstrate the solution we take an example with three tasks whose characteristics are given in Table 7.1. The timing analysis is shown in Figure 7.4. The scaling factor derivation for the first task is straightforward. The derivation for the other two tasks is shown in the figure. The common scaling factor for this example task-set is 1.6363.

We compare the scaling factors obtained by taking the approach in this chapter as opposed to the critical instant approach followed in chapter 5 to appreciate the benefits. If this task-set was subjected to the approach in chapter 5 then the common scaling factor would be 1.3636. Using the approach

described in this chapter we get a scaling factor of 1.6363. This is a huge gain considering that it is a multiplicative factor and not additive. This will become more evident if we express the improvement in execution times as percentages.

Figure 7.4: Operation of example task set
Chapter 8

Admission Control for Real-Time Communication

The model assumptions in this chapter are based on the Real Time Channel model described in Chapter 2. Admission control is the mechanism by which multiple real-time connections can simultaneously share the resources of a packet switching network without resulting in congestion. Further, the connections are guaranteed a particular quality of service (QoS) that is initially (at connection set up) agreed upon. Admission control comes into play when a new RT channel is being requested. An RT channel (or a connection request) is accompanied with a QoS list that describes the requirements of this connection. Popular QoS requirements in the literature of distributed real-time systems are - throughput, latency (or deadline), packet loss tolerance [17, 28, 10, 35, 32] etc.

The mechanism used to determine the admissibility of a real-time channel involves verifying at each intermediate link (along the path) in turn whether the RT channel's QoS requirements can be guaranteed. If a channel's requirements can be met at each of the intermediate links then we can accept the channel. If however, the channel's requirements cannot be met at any of the intermediate link then we can reject the channel. In fact the first such link that
deems the channel inadmissible is sufficient to confirm that the channel would not be admissible.

In order to test whether a channel's requirements will be met at an intermediate link we have to know its deadline and its period at each of that link. Finding the period is straightforward according to the phase adjustment mechanism. However we do have to derive the deadline of the RT channel at intermediate links. Since the service time of the channel on each of the links is the same one way to derive the deadlines would be to divide the slack of the RT channel equally among the intermediate links. However, if one wishes, one can use a more sophisticated heuristic [15, 4, 47] to derive these deadlines. This reduces the problem of finding the admissibility of an RT channel to be equivalent to solving the admissibility at each of the intermediate link [11, 18]. From here onwards when we refer to the admissibility of an RT channel we mean its admissibility at an intermediate link.

Now, the question that admission control has to answer when accepting a new connection can be broadly phrased as:

- Given the QoS requirements of a new RT channel is it possible to accept this channel without violating the QoS guarantees made to RT channels that have already been accepted?

The principle followed by researchers (for example Tenet [8, 9]) in the design of an admission control scheme is based on verifying, whether the resources available on the path of the newly requested RT channel are sufficient even in the worst possible case, to
1. provide the new RT channel with the QoS it needs and,

2. allow the guarantees offered to all the existing RT channels to continue being satisfied.

The above verification depends upon the kinds of QoS parameters allowed. The most important QoS parameter of concern to real-time system designers is the meeting a latency bound (deadline). We restrict our interest to this parameter. There are two tests that are relevant in this context:

- Schedulability Test: Does the addition of the new channel to the already established channels using this link cause either the new channel or one of the already established channels to miss their deadline?

- Buffer Space Test: Is the available buffer space at the link sufficient to allow the messages of the new channel to be stored for a length of time equal to the delay faced by the channel at this link?

Different approaches to the admission control problem (in real-time systems) will differ in the way the above two questions are answered. Therefore, a study in admission control reduces to the study of these tests. The buffer space test has been successfully addressed by the Tenet group [9]. We concentrate mainly on the schedulability test because it is our belief that there is room for improvement here. In particular, there are many situations that have not been considered in this context. We broadly classify two situations which differ in terms of the assumptions made about the scheduling mechanism used to schedule channels on the intermediate links.
8.1 Dynamic Scheduling of RT Channels

The Tenet schedulability test involves a deterministic test at each intervening link along the path. An assumption is made that the scheduling mechanism used at an intermediate link is based on the EDD [9] (earliest due date or popularly referred to as the earliest deadline first). The test is based on extending the fundamental task scheduling result by Liu and Layland [24] to message communication. It can be summarized as follows: A given set of RT-channels (at a particular link) is schedulable\(^1\) by the EDD policy if the sum of the utilizations of the RT channels is less than one. The utilization of the \(i^{th}\) RT channel whose characteristics are a message service time of \(m_i\) and a message inter-arrival time of \(g_i\) is given by, \(u_i = \frac{m_i}{g_i}\). If the current total utilization at a link is \(U_{\text{det}}\) then the utilization as a result of accepting the new connection \((i^{th})\) would be \(U_{\text{det}} = U_{\text{det}} + \frac{m_i}{g_i}\), and the schedulability test would be to check whether \(U_{\text{det}} < 1\).

We have taken a different approach to the schedulability test that is based on the scaling problem defined in Chapter 4. The principle involved in the test can be described as follows. At each intermediate link an admittance measure is computed that essentially captures the tightness of the traffic already passing through the link. A new connection request is allowed or disallowed depending upon whether a specific relationship between this measure and the new connection's characteristics is satisfied. The computation of the admittance measure is dependent upon the choice of the scheduling mechanism and the characteristics of the connections already accepted. Further the tested

\(^1\)all the RT channel deadlines will be guaranteed to be met.
relationship referred to above, is a heuristic comparison between the current admittance measure and the new connection's characteristics.

The admittance measure we use is the scaling factor (refer to Chapter 4) with which the message service times of channels already accepted can be multiplied by, so that the channels' requirements can still be guaranteed. The new connections' characteristics are captured by its utilization demand. The heuristic used can be explained as follows. Intuitively, the greater the scaling factor greater is the potential to allow a new connection. Further, the room for accommodating new connections is intuitively captured by the term, \( \frac{s_{n-1}}{s_{n-1}} \). This expression, can be viewed as the percentage improvement possible in the utilization of the existing channels. The expression can be simplified into the form, \( 1 - \frac{1}{s_{n-1}} \). We show later, how this heuristic turns out to be equivalent to the deterministic test of Tenet (in the context of EDD that is).

The following table, shows a comparison of our approach (using the scaling factor) and Tenet's approach. The scheduling mechanism chosen at a link is assumed to be the EDD. We later show how the two approaches are equivalent.

<table>
<thead>
<tr>
<th>Approach</th>
<th>Computation</th>
<th>Test</th>
</tr>
</thead>
<tbody>
<tr>
<td>Tenet</td>
<td>( U_n \leftarrow U_{n-1} + \frac{m_a}{s_n} )</td>
<td>( U_n &lt; 1 )</td>
</tr>
<tr>
<td>Scaling</td>
<td>( s_{f_{n-1}} ) (precomputed)</td>
<td>( \frac{m_a}{s_n} \leq 1 - \frac{1}{s_{f_{n-1}}} )</td>
</tr>
</tbody>
</table>

The second column in the table gives the computation that has to be done in order to test for the admissibility of a new channel. This test can either be done at the time the new connection is made (Tenet's approach) or it can be
precomputed (our approach). The advantage of completing this computation before the channel is requested is that it will cause minimal delay in ascertaining admissibility. Further, it affords the designer to attempt a more sophisticated computation because it is done prior to the actual channel admission test. The third column gives the test performed when a new connection is requested.

We now show how the two approaches given in the table are equivalent. In the case of Tenet, the admissibility test can be viewed as a simple comparison to check if the total utilization resulting from the addition of the new channel is above the allowed bound (1). Observe that the computation in the second column involves the characteristics of the new connection, thus making it a computation that has to be performed when the new connection is requested. We can however, modify Tenet's approach so that the computation (just compute $U_{n-1}$) is independent of the new channel characteristics and can thus be done before hand. Further, this modification would result in the test changing to: $\frac{m_a}{g_n} \leq 1 - U_{n-1}$.

The reader is referred to Chapter 5 for a discussion of the scaling factor problem. More specifically, in section 5.2, a special instance of this problem is identified when the subset to be scaled $S$ is the same as the given task-set $T$. It was shown that the common scaling factor (in the case of EDF) is then given by the reciprocal of the total utilization of the RT channels.

$$s f_{n-1} = \frac{1}{\sum_{1 \leq i \leq n-1} \frac{m_a}{g_i}} = \frac{1}{U_{n-1}}$$

The test in third column can therefore be interpreted as the $\frac{m_a}{g_n} \leq$.
Therefore, we see that the two approaches reduce to be the same. Observe that, the computation of the scaling factor, $s_{f_{n-1}}$ is more involved if the scheduling mechanism is not EDF. This is the subject of the following section.

### 8.2 Fixed Priority Scheduling of RT Channels

Our next concern is to extend the approach described in the previous section to general fixed priority preemptive scheduling mechanisms. Note that the Tenet approach is only valid for dynamic preemptive scheduling. We use the same approach to admissibility as described in the previous section, except that we have to pay special attention to the computation of the scaling factor. We concentrate our attention to extending our approach to incorporate the Rate Monotonic Scheduling (RMS) mechanism (a particular instance of the fixed priority preemptive scheduling mechanism). An extension of the approach to Deadline Monotonic Scheduling and more generally to any arbitrary fixed priority scheduling mechanism is straightforward.

As we already have seen in Chapter 4, there is no straightforward way to compute the scaling factor of a set of tasks (read as RT channels in the present context) scheduled by a general fixed priority scheduling mechanism. However, in the particular case of RMS, we can find a non-optimal scaling factor that is given by:

$$s_{f_{n-1}^{RMS}} = \frac{(n-1)(2^{1/(n-1)} - 1)}{U_{n-1}}$$

This factor is not optimal in the sense that it is possible to improve it further. Unlike task schedulability where we were interested in an optimal scaling factor, in the current context (admission control that is) the above computation does
carry a certain merit as will be demonstrated shortly. Though the heuristic used in the admissibility test reduced to the deterministic test in the context of EDD, this is not necessarily true in the current context. In other words, failing to pass the heuristic test does not necessarily imply that the new channel will interfere with the schedulability of the already existing channels. This implies that, using the heuristic it is possible that a new channel request is rejected even though it could have been accommodated.

An alternative to the above computation is to use a more precise computation, one which would help us obtain an optimal scaling factor. We have shown in Chapter 4, how such a computation works. This alternative is appealing in its ability to reduce the number of rejections (as described in the previous paragraph). However, it does not necessarily guarantee 100% admissibility. 100% admissibility is said to be achieved if the test never rejects a new channel that would have not interfered with already accepted channels. The failure of this alternative to ensure 100% admissibility is due to the fact that though the scaling factor computation is precise, the comparison in which it is used is a heuristic.

It is important to observe that, the scaling factor computation is not performed at the time of a channel request and therefore we can afford the cost involved in finding an optimal scaling factor. However, if the benefit (reducing the number of rejections) obtained by using the optimal scaling factor is not large enough (compared to using the non-optimal computation), we cannot justify it. Since, the basis of the test is a heuristic, the only way one can confirm the benefits is to perform a simulation study.
Simulation Study

The goal of this study was to compare the two alternatives for admission control (described above) when the underlying mechanism used to schedule the RT channels is the Rate Monotonic Scheduling. An RT channel is characterized, among other parameters by the source and destination of the channel. This information is used to find the route of the RT channel. As already described the admissibility test of an RT channel that traces a route of, say \( k \) links, reduces to ascertaining its admissibility at each of the \( k \) links in turn. Therefore, we restrict our study to admissibility at a single link. From here onwards when we refer to the characteristics of an RT channel we don't mean its end-to-end characteristics but its characteristics at an intermediate link.

We use the following notation in the following discussion:

\[
x \sim U(a, b)
\]

indicates that the random variable \( x \) is uniformly distributed over the interval from \( a \) to \( b \).

\[
x \sim N(\mu; \sigma)
\]

indicates that the random variable \( x \) has a normal distribution with mean \( \mu \) and standard deviation \( \sigma \).

There are two major steps to the simulation study:

1. The workload generation. The workload of interest to us is the generation of characteristics of \( n \) RT channels at a link. We would like to characterize the workload with a set of parameters that capture its essence. We use the following two parameters to characterize (and distinguish between) workloads:
(a) The utilization $U$, of the set of RT channels is used to identify the cumulative demand of the workload.

(b) The laxity factor $\kappa$, dictates in addition the closeness of the deadline to the end of the period of the RT channels.

2. The simulation of the alternatives and their comparison. The two alternatives of concern to us are, using the non-optimal scaling factor vs. using the optimal scaling factor in the admissibility test. The details of the comparison are explained later.

Before we explain the generation process, it is important to understand what we are attempting to generate. We are interested in generating a workload of $n$ RT channels with a total utilization of $U$. For each RT channel $C_i$, we wish to know its service time $m_i$, its inter-message generation time $g_i$ and its deadline $d_i$.

The following parameters were used in the generation process.

$n$: The number of RT channels in the link.

$m$: The mean service time of an RT channel.

$U$: The total utilization of the $n$ RT channels. The utilization of an RT channel $C_i$ with service time $m_i$ and inter-generation time of $g_i$ is given by $m_i/g_i$.

$\kappa(0 < \kappa < 1)$: Is the laxity factor.

$\mu_l(0 < \mu_l < 1)$: This parameter controls the laxity of an RT channel. The deadline of an RT channel $C_i$ with a laxity of $l$ is given by $m_i + l \times (g_i - m_i)$.
Therefore, greater the value of \( l \) (directly controlled by \( \mu_l \)), closer is the deadline to the period and more is the room for meeting its deadline.

\( \sigma_l \): The standard deviation of the normal distribution of the laxities of the channels. We constrain this parameter so that following conditions hold:

\[
mu_l - 3 \times \sigma_l > 0 \quad \text{and} \quad \mu_l + 3 \times \sigma_l < 1
\]

The above two conditions guarantee \cite{16} that the majority (\( \approx 99.98\% \)) of the samples derived from the distribution, \( N(\mu_l, \sigma_l) \) are within the bounds(0 and 1).

The approach taken for workload (\( n \) RT channels) generation can be described as follows. We generate the characteristics of each RT channel \( C_i \) in turn.

1. The service time \( m_i \) of channel \( C_i \) is derived from a uniform distribution over the range \([1, 2 \times m]\):
   \[
m_i \sim U(1; 2 \times m)
   \]

2. The utilization of \( u_i \) of channel \( C_i \) is derived from a uniform distribution over the range \([0, 2 \times \frac{U}{n}]\):
   \[
u_i \sim U(0; 2 \times \frac{U}{n})
   \]

3. The inter-generation time (or period) \( g_i \) of channel \( C_i \) is obtained by using its service time and utilization already generated above, as:
   \[
g_i = \frac{m_i}{u_i}
   \]
4. Channel $C_i$'s deadline $d_i$ is obtained as:

$$d_i = m_i + \kappa \times (g_i - m_i)$$

where $\kappa \sim N(\mu_l; \sigma_l)$

A special case of interest in the simulation (discussed below) we need a workload where the laxity factor of the RT channels is a constant. We can generate a workload with such a characteristic by assigning the parameter $\sigma_l$ to be equal to zero and the parameter $\mu_l$ to equal the constant desired.

Having generated the workload we are now in a position to compare the two heuristic alternatives against the generated workload. As explained before the test mechanism we use to determine whether a new RT channel $C_n(m_n, g_n, d_n)$ can be admitted at a link, having already accepted $n - 1$ RT channels is given by:

$$\frac{m_n}{g_n} \leq 1 - \frac{1}{s_{f_{n-1}}}$$

Where the term $s_{f_{n-1}}$ is the factor by which the $n-1$ (already accepted) channel service times can be scaled without violating their schedulability requirements. The two alternatives we are interested in comparing differ in the way this scaling factor is arrived at.

- $R$: Uses the non-optimal computation of $s_{f_{n-1}}$ given by Equation 8.1.

- $S$: Uses a precise (optimal) computation of the $s_{f_{n-1}}$ described in Chapter 4.

In order to explain the criteria that were chosen for the comparison it is important to understand that the workload generated (of $n$ RT channels)
is arbitrary in the sense that they can be either admissible (together) or not. For a given workload however, we can test whether it is schedulable or not. In other words, whether all the RT channels can be accommodated together or not. We refer to the outcome of this test as the admissibility (denoted by \( A \)) of the workload.

Observe that the above test finds the admissibility of a workload whereas, the heuristics are designed to test whether a given RT channel can be admitted to an already existing list of RT channels at a link. In other words, the outcome \( A \) can be either, \( A_{\text{yes}} \): the workload can be admitted together, or \( A_{\text{no}} \): the workload is not admissible together. On the other hand, the outcome of the heuristic \( H (R \text{ or } S) \) test can be either, \( H_{\text{yes}} \): admit the new channel, or \( H_{\text{no}} \) do not admit the new channel. However, the heuristic \( H \)'s decision can be compared against \( A \) by defining the following criteria:

1. If the heuristic \( H \) arrives at the decision \( H_{\text{yes}} \) when the workload is in fact admissible (\( A_{\text{yes}} \)), then we say that the heuristic has succeeded on a **YES** match.

2. If the heuristic \( H \) arrives at the decision \( H_{\text{no}} \) when the workload is in fact inadmissible (\( A_{\text{no}} \)), then we say that the heuristic has succeeded on a **NO** match.

3. If neither criterion 1 nor criterion 2 are met then we say that the heuristic has failed.

Note that the reason for having two criteria for a match is because the generated workload was arbitrary in the sense that it could either be feasible
or not. While we are primarily interested in a heuristic’s ability to admit (reach a YES match that is) an RT channel, we cannot ignore the impact of an incorrect decision. The ability of a heuristic to reject infeasible workloads (captured by criterion 2) is important in that it gives us an idea about the heuristic’s sensitivity. For example, it is possible that the heuristic admits a new channel to only realize later that it would result in one or more of the channels’ guarantees being violated.

For a given total utilization $U$ and number of channels $n$ (input parameters), the simulation involves generating workloads of $n$ RT channels and testing the admissibility of each of them. Before we use one of the two heuristics ($\mathcal{R}$ or $\mathcal{S}$) to determine whether they admit a given channel, we first ascertain the admissibility of the workload ($\mathcal{A}$ described before). Next, for each RT channel (say $C_i$) in turn we test its admissibility (using a heuristic) assuming that the $n - 1$ other channels have already been accepted. The test is repeated with the two heuristics we are attempting to compare. If the heuristic we are testing is say $\mathcal{R}$, then the outcome of the test can be one of $\mathcal{R}_{yes}$ (admit the channel $C_i$) or $\mathcal{R}_{no}$ (don’t admit the channel $C_i$). We now compare this outcome against the outcome from the admissibility test for the workload $\mathcal{A}$ which was already computed. The comparison follows the criteria explained before. With respect to this channel we record whether the heuristic achieved a match (could be a YES or NO) or has failed. The simulation records the same for each channel in turn and obtains the heuristic’s performance on this particular workload (This is repeated for the other heuristic also).

The performance of a heuristic for a given workload is characterized by three parameters:
1. The percentage of (the total $n$ admissibility tests) tests that result in a
YES match.

2. The percentage of (the total $n$ admissibility tests) tests that result in a
NO match.

3. The percentage of (the total $n$ admissibility tests) tests that result in
failure.

Observe that, the generated workload is only one of an almost infinite
possible workloads with the same input parameters. Therefore we repeat the
above experiment for a large number of workloads and take an average perfor-
mance. Further we repeat this for different values of $\kappa$ (or $\mu_i$ and $\sigma_i$). The
results of the simulation are presented in Appendix A.

Simulation Results

The performance measure of primary interest to us is the admissibility of a
heuristic. And, we are interested in comparing the two heuristics to see which
of the two is better at admitting channels. Therefore, the graphs we present
here compare the performance using the percentage YES match (see above).

Recollect that, the heuristic $R$ assumes that the underlying scheduling
mechanism is the rate monotonic scheduling. It has been shown that the RMS
is an optimal scheduling mechanism [20] if the deadlines of tasks are a constant
factor of their periods. Therefore, we assume that the parameter $\kappa$ is a constant
and not derived from a distribution. This assumption was made in order to
choose a scenario that is favorable to both heuristics (and not biased to either).
This assumption however has no impact on the second heuristic $S$. 
Each graph is identified by the number of channels considered and the parameter $\kappa$. The $z$-axis gives the total utilization of the workload and the $y$-axis gives the success of the heuristic. For low utilizations (less than 50%) there is no need to do a complex test because the demand can be easily met. We chose four different values of the number of channels (4, 8, 12, 16) and varied the parameter $\kappa$ between 0.5 to 1.0. It was observed that values of $\kappa$ less than 0.5 resulted in too many channels missing their deadlines.

**Observations**

- For low utilizations (less than 0.7) we observe that both the heuristics have a similar admissibility. Given that the heuristic $\mathcal{R}$ is less expensive (computation time-wise) than $\mathcal{S}$, under conditions of low utilizations one can choose the heuristic $\mathcal{R}$.

- For a given value of $n$ and $\kappa$ we observe that the admissibility of heuristic $\mathcal{R}$ falls abruptly beyond a point on the $x$-axis given by the utilization bound. For example, in Figure A.6 we can see that the heuristic $\mathcal{R}$ begins to reject channels when the total utilization crosses beyond 0.72.

- The performance of $\mathcal{S}$ degrades gracefully beyond the utilization bound. For example, in Figure A.6 we can see that the heuristic $\mathcal{S}$ continues to admit channels up to a total utilization of 0.92. The probability of acceptance decreases gradually (and steadily) however. This implies that the heuristic has a better ability to adapt to temporary overloads [43, 26] (increased demand from one of the channels) in the network traffic.

- As the number of channels increases, the performance degradation beyond
the utilization bound is slower in the case of heuristic $S$. This goes on to support the ability of the heuristic to adapt to temporary overloads (increase in the number of channels). The two sources of overload have been successfully handled by the heuristic $S$.

- As the number of channels increases the success of the heuristic $S$ improves compared to the heuristic $R$.

- In conclusion we can say that for low utilizations both heuristics have similar performance (however one should prefer the heuristic $R$ due it computational ease) but, at high utilizations $S$ far outperforms $R$. Further, we can justify the cost of computation involved in $S$ by noting that the computation can be done before the actual channel request is made.
Chapter 9

Summary of Results

As an example to demonstrate the results reported in this thesis, we choose the "Olympus Attitude and Orbital Control System" (AOCS). A detailed case study of this real-time system can be found in [5, 46]. The AOCS subsystem of the Olympus satellite\(^1\) acquires and maintains spacecraft positions as desired. A detailed analysis of this system was performed by A. Burns and his colleagues, as a result of which they have summarized a list of tasks (Appendix B, Figures B.1, B.2 and B.3) that capture the system's functionality. They have identified mainly two classes of tasks viz., periodic (Figures B.1, B.2) and sporadic tasks (Figure B.3).

The class of periodic tasks in the AOCS case-study are consistent with our definition and treatment of periodic tasks in this thesis. Sporadic tasks on the other hand are tasks whose periodicity and arrival time are not known. However, there is a known minimum interval between successive arrivals of these tasks. Also the arrival time parameter of a sporadic task is not known a priori due to the nature of these tasks. Sporadic tasks typically occur due to events such as exceptions and interrupts which are triggered by a logical state.

\(^1\)The Olympus satellite was launched in July 1989 as the world's largest and most powerful civil three-axis-stabilized communications satellite. It provides direct broadcast TV and 'distance learning' experiments to Italy and Northern Europe.
of the system or an external event. These events are therefore a function of the run-time characteristic of the system.

The treatment in this thesis has been restricted to handling only periodic tasks, however we can accommodate sporadic tasks by making a few observations about their behavior. The minimum inter-arrival time parameter associated with a sporadic task is a lower bound on its periodicity. For the purpose of this chapter we choose the periods of sporadic tasks to have values ranging from the minimum to the average periods of periodic tasks. Accordingly the chosen values of periods for sporadic tasks have been listed in the tables. Further, we have chosen the arrival times of these tasks to be zero, in other words that the first occurrence of these tasks is at time $t = 0$. Clearly, this is only one of the many possibilities but is sufficient to demonstrate our point of interest here.

The following sections use this task-set to demonstrate the results reported in chapters 5 to 7.

9.1 Scalability in Uniprocessor Systems

The above task-set (say $T$) is given for a uniprocessor system, where all the tasks are known to execute on a central control computer. In order to apply the result given in Chapter 5 we have to choose a subset (say $S$) of tasks in the task-set that are to undergo scaling. For a lack of better knowledge about the tasks we pick $S = T$, i.e., we are interested in finding the maximum common scaling factor for all tasks in the task-set. Table 9.1 gives the results of this analysis:

Scaling Factor for $S = 1.7941$

The mechanism used to find the scaling factor in the uniprocessor scenario is based on the critical instant assumption. This result can be easily improved by using a more precise mechanism that is based on the results in chapter 7. However, as discussed in chapter 4 the critical instant assumption is more suitable in uniprocessor systems. Further, it makes the scaling factor computation more efficient and cheaper (in terms of processing time).

Another perspective of the scaling factor can be expressed in terms of the utilization. The utilization of a task $T_i$ is given by the ratio of its execution time to its periodicity, $\frac{e_i}{p_i}$. The total utilization of the task-set before scaling is given by:

$$U = \frac{e_1}{p_1} + \frac{e_2}{p_2} + \ldots + \frac{e_n}{p_n}$$
For the task-set in our case study this is given by: 0.4619. The utilization of the task-set after the scaling is performed is given by:

\[ U' = s_f \times \sum_{i \in S} \frac{e_i}{p_i} + \sum_{j \in T - S} \frac{e_j}{p_j} \]

Where, \( s_f \) is the maximum common scaling factor for the task in \( S \). In our example, \( S = T \), therefore the second term in the above equation is zero. The new utilization is now given by \( 1.7941 \times 0.4619 = 0.8287 \). This achievable improvement in utilization is promising for the application with regards to, scalability, execution time estimation, portability and fault-tolerance as described in chapter 3.

## 9.2 Schedulability of Task-Sets with Arrivals

As described in chapter 4, solving the problem of scalability in end-to-end real-time systems involves solving the two problems of (i) schedulability of tasks on a single component without ignoring arrival times and, (ii) scalability of tasks with non-zero arrival times. The first of these problems was discussed in chapter 6.

This section discusses this result by applying it the AOCS case-study. Our first example involves, treating the AOCS as an end-to-end task system with each task comprising only one sub-task which runs on the only component in the system, i.e., the processor. Now, the determining the schedulability of the tasks involves computing their worst-case response times. For comparison purposes, the following table (9.2) gives the worst-case response times using two different mechanisms, i.e., the critical instant approach \( (WC^c) \) and, the approach described in chapter 6 \( (WC^r) \). The third column gives the percentage
improvement in the response time obtained by using our precise approach as opposed to the critical instant approach. The fourth column gives the slack savings achieved by using our approach. Slack savings (in percentage) is given by the formula:

\[ ss_i = \frac{WC^c_i - WC^r_i}{d_i - e_i} \times 100 \]

While the percentage improvement obtained does have some merit in explaining the need for a more precise approach, the slack savings parameter qualifies the ability of a task to accommodate task interdependence (e.g., precedence), withstand temporary overloads, accommodate aperiodics in the system and restrict jitter in end-to-end systems.

As a second demonstration of the results in Chapter 6, we consider an actual decomposition of the task-set into sub-tasks. The chosen decomposition
is only one of the possible decompositions obtained by arbitrarily dividing and assigning tasks to four components. The decomposed task-set is given in Figure 9.3.

The following tables (9.4, 9.5, 9.6, 9.7) give details of the analysis of each component in turn. The parameter of the sub-tasks that run on the first component $R_1$, are directly inherited from the parent. Further, the deadline parameter is not required in this problem since we are only interested in finding the worst-case response times of tasks, which are given by the sum of the response times of their individual sub-tasks. The arrival time parameter of sub-tasks on component $R_2$ (and subsequently $R_3$ and $R_4$) are obtained by the phase adjustment mechanism.

The following table (9.8) compares the resulting worst-case response times of tasks with their deadlines. Clearly, all tasks meet their deadlines.

</tbody>
</table>

Further, by comparing these response times against those in table 9.2 we observe the enormous improvement in response times of tasks.

### 9.3 Scalability in End-to-End Systems

As mentioned in the previous section, the second issue to be addressed in solving the scalability problem in end-to-end systems is: scalability of tasks on a single component with non-zero arrival times. This was the subject of Chapter 7. In this section, we first compare the scaling factor obtained by incorporating task arrival times against, that obtained by using the critical instant assumption

(Chapter 5). Table 9.9 gives the summary of this comparison. The maximum common scaling factor by the precise approach is under the second column ($sf(actual)$) and that obtained by the critical instant assumption in Chapter 5 is under the third column ($sf(orig)$). The task-set is assumed to run on a single component and accordingly each task has a single sub-task. The subset $S$ that has to be scaled is same as $T$. The common scaling factor $sf(actual)$ is 2.1295 which is clearly greater than 1.7941 obtained by the other mechanism. In terms of utilization the resultant task-set utilization is 0.9836 or 98.36%. Note that, ideally one would expect to be able to obtain 100% utilization on scaling, however, this is not achievable in the case of static fixed priority schedulers.

Recall that in Chapter 4 problem of scalability of task-sets in end-to-end real-times systems comes in two different forms: task changes and component

changes. The following modification of the case study demonstrates how our approach to finding the precise scaling factor can be applied in an end-to-end scenario where component changes can occur. The same decomposition used in the previous is used here. The following tables (9.10, 9.11, 9.12 and 9.13) give the details of the scaling factor computation for each of the components. The deadline parameter for each sub-task is obtained by using a heuristic that divides the slack of a task among its sub-tasks in a weighted proportion of their execution times. Now, For example, if the set of components that undergo change are \{R_2, R_4\} then the scaling factor is $\min \{5.3949, 6.4935\}$ which is 5.3949.

Chapter 10
Conclusions

The significant contributions of this thesis can be broadly summarized as follows:

• We have addressed the need to handle complexity in real-time systems in all phases of system design, viz., design, development and maintenance.

• We have presented a novel perspective to analyzing real-time systems that in addition to ascertaining the ability of a system to meet task deadlines also qualifies these guarantees.

• The need to qualify guarantees was shown to arise from the following scenarios pertinent in the design, development and maintenance of real time systems:

  – *Scaling application requirements*: As a system evolves the functionalities of tasks expand, reflecting in terms of increase in code size and/or improvement in data handling of tasks. This increase affects the schedulability guarantees made using the previous execution times. Therefore, what we are interested in is, finding a factor by which the execution times can be scaled (capturing the data handling change) without invalidating the schedulability guarantees.
- Task execution time estimation: Using mean task execution times as opposed to worst-case execution times in schedulability analysis reduces the pessimism (leading to over design and under-utilization of resources) inherent in the computation. Unfortunately however, using the mean could lead to cases where the guarantees provided by the schedulability analysis could be invalid (The number of such cases being determined directly by the variance in the computed mean execution time). Therefore, it is necessary to accommodate the variance information along with the mean (for task execution times).

- Porting applications: Any analysis performed (to guarantee performance) assuming particular values of task execution times becomes invalid once the target platform changes. For example, a faster processor could result in a lower execution time (not invalidating the analysis), but a slower processor would surely have an adverse effect on the schedulability analysis. As a system evolves, though in general the overall system is likely to improve, the performance of individual components (some processors for example) might not always improve. Another instance where a target platform is in general slower, arises in the case of prototype building and testing [51].

- Fault Tolerance: It is common practice to provide fault-tolerant operation by the use of redundant components (often at least one secondary component). In general, secondary components provide only a minimal functionality (sufficient to keep the system operational till the primary is fixed) and therefore tend to be slower. Any schedu-
lability analysis guarantees provided with the primary component as the target will be invalid once the system falls back onto the secondary.

- The scaling factor problem (refer to Chapter 4) defines a quantitative measure that in essence captures the above mentioned scenarios under a uniform framework. The problem is generic in the sense that it leaves such particulars as:
  - the scheduling mechanism,
  - deadline to period relationship, and,
  - arrival information,
open. For example an instance of the problem could be to find the scaling factor when the assumed scheduling mechanism is a static fixed rate monotonic priority assignment, the task deadlines are less than or equal to their periods, and, the task arrivals are arbitrary.

- The scaling factor problem was first formulated in the context of uniprocessor real-time systems. This scenario can be more generally referred to as the single component scenario. The tasks running on the single component in question are evaluated with regards to their ability to meet their requirements (processing and deadline). Further, we compute a measure that gives us the ability of these tasks to scale-up without violating their guarantees. One important assumption made in this context was that the arrival times of the various tasks can be assumed to be zero. This assumption has helped us in using the critical
instant argument to ascertain task schedulability and also in finding the
scaling factor. We demonstrated some justifications for the use of this
argument, particularly in the context of single component systems with
independent tasks.

• Unlike uniprocessor systems, in end-to-end systems, the scaling factor
problem appears in two different scenarios, viz., component changes and
task changes. We showed how both these scenarios arise and how they
can be reduced to solving the following fundamental problems:

  - Compute sub-task parameters of periodicity and deadline.
  
  - Given a task-set $T$ of $n$ tasks (with non-zero arrivals) executing on a
single component, find the worst-case completion times of all tasks
in the task-set.

  - Solve the scaling problem when the tasks have arbitrary non-zero
arrivals.

The first of the above problems involved finding sub-task periodicities
by a technique called phase adjustment and sub-task deadlines by using
a heuristic based on proportional division of the total slack of a task
among its sub-tasks. Our solution to the second problem is the subject
of Chapter 6. This problem has been observed to be relevant in many
other contexts in real-time systems, and a discussion to this end can be
found in the same Chapter. Chapter 7 presents a solution to the third
problem listed above. The complexity is introduced mainly by having to
accommodate task arrivals into the analysis. However, this consideration
adds validity to our work and also bridges the gap between theory and
practice by better modeling the behavior of current complex real-time systems.

• Finally we presented an application of the scaling factor problem in the context of real-time communication. The problem considered is the admission control of real-time channels (Ferrari et al. [9]). Admission control is the mechanism by which multiple real-time connections can simultaneously share the resources of a packet switching network without resulting in congestion. The mechanism used to determine the admissibility of a real-time channel involves verifying at each intermediate link (along the path) in turn whether the RT channel’s QoS requirements can be guaranteed. If a channel’s requirements can be met at each of the intermediate links then we can accept the channel. If however, the channel’s requirements cannot be met at any of the intermediate link then we can reject the channel. In fact the first such link that deems the channel inadmissible is sufficient to confirm that the channel would not be admissible.

This problem is shown to be analogous to the end-to-end schedulability problem with the exception that the solution cannot be based on evaluating a channels admissibility by doing a complete (expensive) schedulability test. To this end, we proposed a heuristic approach that is based on the scaling factor computation. The room for accommodating a new channel into a system is expressed in terms of the maximum scaling factor with which the requirements of the channels already in the system can be scaled without violating their guarantees. This expression is then compared against the requirements of the new channel that is to be con-
sidered for admission. The expression being of a heuristic nature, we resorted to a simulation study (details in Chapter 8), the results of which have demonstrated the effectiveness of our approach.

Appendix B

The Olympus Attitude and Orbital Control System

The first two tables list the periodic tasks in the system and the last table lists the sporadic tasks. The parameter of periodicity of sporadic tasks is a derived parameter chosen for our study and not specified in the original study. The first parameter, critical level, is not used in our study, but essentially adds to the priority information of tasks. In general we could have had HARD, SOFT or FIRM categories of criticality and a special category called INTERRUPT, that implies that the corresponding task should be executed non-preemptively. In this case study there is only one task that is not categorized as HARD. Since this task (BUS_INTERRUPT) is assigned the highest priority, it is guaranteed to run un-preempted, satisfying the requirement of tasks that are categorized as INTERRUPT.

The periodicity of sporadic tasks was chosen randomly to lie between the minimum inter-arrival and the average periodicity of periodic tasks. The minimum inter-arrival time parameter of sporadic tasks gives a lower bound on successive arrivals and is very rarely encountered in practice. Therefore, even if two successive arrivals of a sporadic task do occur at this minimum interval the probability of the next instance also occurring at this interval is very remote.
