Abstract

Multi-layered round carbon particles (onions) containing tens to hundreds of thousands of atoms form during electron irradiation of graphite carbon. However, theoretical models of large icosahedral fullerenes predict highly faceted shapes for molecules with more than a few hundred atoms. This discrepancy in shape may be explained by the presence of defects during the formation of carbon onions. Here, we use the semi-empirical tight-binding method for carbon to simulate the incorporation of pentagon-heptagon defects on to the surface of large icosahedral fullerenes. We show a simple mechanism that results in energetically competitive derivative structures and a global change in molecular shape from faceted to round. Our results provide a plausible explanation of the apparent discrepancy between experimental observations of round buckyonions and theoretical predictions of faceted icosahedral fullerenes.
INTRODUCTION

Spheroidal multi-layered carbon nanoparticles, dubbed buckyonions, have been observed during electron irradiation of graphitic particles.\textsuperscript{1,2} These molecules have interesting mechanical and energetic properties which make them of great experimental and theoretical interest.\textsuperscript{3-5} Transmission electron micrographs (TEM) of buckyonions have provided a wealth of knowledge about their shape and structure as well as more detailed information about inter-shell spacings and local areas of non-uniformity (defects).\textsuperscript{1,6,7}

Local areas of high defect density have been observed on the surface of the individual shells of buckyonions at room temperature. However, at experimental temperatures of 700° C, TEM of buckyonions show highly uniform defect-free round layers extending to radii of 50 nm or more, suggesting removal of defects with increased thermal energy.\textsuperscript{8} Radial compression of these buckyonions due to sputtering and carbon loss results in extremely high pressures in the buckyonion interior and significant changes in the inter-shell spacings as a function of proximity to the onion core. Remarkably, pressures inside onions have been shown to exceed that necessary to effect a phase transition from $sp^2$-carbon to diamond.\textsuperscript{8} Inter-shell spacings range from about 0.31 nm at the exterior of buckyonions, near the van der Waals interaction distance between layers of graphite, to as small as 0.22 nm. The observed compression is accredited to radiation-induced interchange of carbon species between shells, resulting in a net flux of carbon out of the buckyonion.\textsuperscript{8,9} Carbon rearrangement and evaporation most likely occur at local areas of high defect density in buckyonion structure during formation. Therefore, radial compression and removal of defects likely occur as two results of the same process.
Each shell of a buckyonion can be modeled as a closed carbon cage, or fullerene. The size of each shell within a buckyonion ranges from the inner-most shell, which is usually smaller than C₆₀-Buckminsterfullerene (C₆₀ BF), to the outer-most shells which contain tens or hundreds of thousands of carbon atoms. Studies on large fullerenes may have interesting implications which apply to each layer within buckyonions, and thus to buckyonions as a whole. In particular, icosahedral (I₉) fullerenes, widely thought to represent lowest energy fullerene isomers for a given molecular size, have been well-characterized in a series of theoretical studies. These molecules are composed solely of five- and six-membered rings. Large I₉ fullerenes possess strongly faceted geometries and include 12 vertices and 20 faces, composed of 5-membered rings and graphene sheets, respectively. A “divide-and-conquer” implementation of density functional methods has predicted two different geometries for I₉ C₂₄₀, each representing a separate energetic minimum: one corresponding to a spherical shape and the other corresponding to a faceted shape. However, results using the Tersoff-Brenner classical potential, tight-binding, MNDO, Hartree-Fock, and density functional methods have clearly shown a unique minimum: that of a highly faceted geometry for I₉ fullerenes larger than C₆₀ BF. This result is in direct contrast with the observed shape of buckyonions under experimental conditions. The predicted geometry of these fullerenes suggests that the curvature strain is localized at the 5-membered rings allowing the I₉ faces, composed of graphene sheets, to remain flat.

In order to gain a more cohesive understanding of the connections between the various observed carbon nanostructures, it is important to reconcile the observed shape of buckyonions with theoretical predictions about the shape of I₉ fullerenes. Work by others has explored the possible effects of van der Waals forces and
axes of observation\textsuperscript{10} on the observed appearance of large $I_h$ fullerenes and buckyonions. While van der Waals studies have shown significant distortion of nanotube\textsuperscript{19}, and buckyonion\textsuperscript{20} walls under particular experimental conditions, a cohesive theory by which the overall shape of buckyonions can be explained in terms of van der Waals forces has yet to be developed. It is unlikely that the axis of observation can explain the discrepancy between $I_h$ fullerene and buckyonion shapes because TEM of buckyonions represent time-averaged images of mobile carbon molecules.\textsuperscript{21} Alignment of buckyonions along a particular axis of observation has not been conclusively demonstrated under these experimental conditions.

Previous studies have examined the role of non-classical ring structure in determining the topology of graphitic surfaces\textsuperscript{10,22,23} These studies have proposed that a balance of positive and negative curvature on the surface of large fullerenes, exerted by five- and seven-membered rings, respectively, may result in an overall spheroidal shape. We have also proposed mechanisms by which seven-membered rings may be introduced on to the surface of large fullerenes via C\textsubscript{2} fragmentation and Stone-Wales rearrangement.\textsuperscript{24} The energetics of these processes have been examined in detail.\textsuperscript{22,25,26}

In this study, we propose a mechanism of 5-7-5 defect introduction via repeated C\textsubscript{2} removal from pentagon-hexagon (5-6) bonds on the surface of $I_h$ fullerenes that is consistent with the observed thermal migration of interstitial species during buckyonion formation. This mechanism and the resulting structures are discussed in detail below. Our calculations indicate that this scheme results in a global change of $I_h$ fullerene geometry from faceted to spheroidal with a loss of only 24 atoms and the introduction of only 12 5-7-5 defects. Quantum chemical calculations confirm a geometry for the resulting molecules consistent with observed buckyonion shape.
The energetics of this mechanism of C$_2$ removal and the resulting structures are also discussed in detail.

COMPUTATIONAL METHODS

Calculations were initially performed using a linear-scaling implementation$^{13}$ of the semi-empirical tight-binding (TB) potential for carbon.$^{27}$ Properties of the tight-binding potential and functional form are discussed thoroughly elsewhere.$^{27}$ For molecules with 60 atoms or less, we performed more rigorous calculations using the 3-21G basis set at the Hartee-Fock (HF) level of theory. All HF calculations were carried out using a development version of the Gaussian suite of programs.$^{28}$ All TB energy values quoted in this paper correspond to molecules with geometries fully optimized by a TB conjugate-gradient scheme. HF energy values were obtained at molecular geometries fully optimized at the 3-21G/HF level of theory.

RESULTS AND DISCUSSION

As discussed above, C$_2$ fragmentation is an important method of introducing defects on to the surface of $I_h$ fullerenes, particularly at high experimental temperatures.$^{29}$ Figure 1 depicts two different mechanisms by which C$_2$ removal may occur on the surface of an $I_h$ fullerene. For illustrative purposes, we perform this C$_2$ removal from the surface of C$_{60}$ BF. In portion A of Figure 1 (Figure 1A), a C$_2$ fragment is removed from a 5-6 bond resulting in an intermediate structure with four dangling bonds, as shown in the middle entry of Figure 1A. Rebonding of these dangling bonds results in a 7-membered ring with two 5-membered rings,
termed a 5-7-5 defect. Details of the C2 loss mechanism were presented in previous publications.\textsuperscript{25,26} In Figure 1B, a C2 fragment is removed from a 6-6 bond of C\textsubscript{60} BF. Again, we see an intermediate structure with four dangling bonds. Rebonding creates an 8-membered ring with two 4-membered rings, a 4-8-4 defect.

The energetics of these two schemes for C2 removal are shown in Table 1. We calculate the energy of C2 removal from a 5-6 bond of C\textsubscript{60} BF as 11.5 eV and 14.0 eV, using TB and 3-21G/HF, respectively. In contrast, we find the energy of reaction for C2 removal from the 6-6 bond of C\textsubscript{60} BF to be 15.8 eV and 17.9 eV, using TB and 3-21G/HF, respectively. Both levels of theory predict approximately 4 eV less energy required to introduce a 5-7-5 defect as compared to a 4-8-4 defect. In order to confirm these results for larger fullerenes, we performed an analogous set of calculations for C2 removal from C\textsubscript{960}, this time using TB only. In this case, we compare the energy of C2 removal from a 5-6 bond of C\textsubscript{960} with C2 removal from one 6-6 bond located in the center of an icosahedral face. We found an energy of 10.0 eV for introduction of the 5-7-5 defect as compared with an energy of 16.7 eV for introduction of the 4-8-4 defect. Here, we see 6.7 eV less energy required for removal from the 5-6 bond rather than a 6-6 bond. Based on these calculations, we predict that 5-7-5 defects, rather than 4-8-4 defects, may play an important role in buckyion formation.

In order to investigate a potential connection between \textit{I}h fullerenes and bucky-onions, we studied the effect of 5-7-5 defects on the shape of \textit{I}h fullerenes. For the 5-7-5 cluster, isolated and surrounded by a graphene sheet, our TB and 3-21G/HF results predict a flat surface. In Figure 2, we compare the shapes of corannulene and a graphene-surrounded 5-7-5 cluster, both fully-optimized using 3-21G/HF. While corannulene is decidedly curved, the 5-7-5 cluster is shown to be flat. The differ-
ence in shape between these two structures provides a key for understanding the topological effect of 5-7-5 defects on the surface of icosahedral fullerenes. By removing a C\textsubscript{2} fragment from a 5-6 bond on each 5-membered ring of an \textit{I\textsubscript{h}} fullerene and allowing full geometry reoptimization, we imposed 12 5-7-5 defects with a total removal of 24 atoms. The resulting molecule we dub C\textsubscript{936} DF for C\textsubscript{936} with defects. Figure 3 compares the shapes of \textit{I\textsubscript{h}} C\textsubscript{960} and C\textsubscript{936} DF along two different axes of observation. Entries A and B show the highly faceted \textit{I\textsubscript{h}} C\textsubscript{960} as viewed along the \textit{C\textsubscript{5}} and \textit{C\textsubscript{2}} axes, respectively. Entries C and D show C\textsubscript{936} DF along the same axes of observation. These pictures clearly demonstrate a dramatic change of shape from faceted \textit{I\textsubscript{h}} C\textsubscript{960} to a much more spheroidal C\textsubscript{936} DF. Figure 4 shows an identical set of pictures for \textit{I\textsubscript{h}} C\textsubscript{3840} and C\textsubscript{3816} DF, the largest system that we studied. As in Figure 3, removal of 12 C\textsubscript{2} fragments drastically changes shape of \textit{I\textsubscript{h}} C\textsubscript{3840} from highly faceted to spheroidal. We attribute these results to a more even distribution of curvature strain on the surface of the molecules with 5-7-5 defects. This interpretation is consistent with the flat topology of both graphene sheets, 5-7-5 clusters, and 5-7-5 defects within graphene sheets. The competition between each of these substructures which want to be flat results in a more even distribution of strain and a spheroidal shape.

The previous C\textsubscript{2} removal scheme was performed for a total of 9 \textit{I\textsubscript{h}} fullerenes, ranging in size from C\textsubscript{540} to C\textsubscript{3840}, resulting in molecules C\textsubscript{516} DF to C\textsubscript{3816} DF. The standard deviation (SD) of the radii of these molecules and those molecules with defects was calculated as a measure of the degree of sphericity of the molecules. A molecule whose radius has a standard deviation of zero, such as C\textsubscript{60} BF, is deemed spherical while molecules with an increasing SD of their radius are increasingly nonspherical. Figure 5 shows the SD of the radii for all molecules mentioned above.
While the SD of the radius of the $I_h$ fullerenes increases steadily with increasing molecular size, reaching 1.15 Å for $I_h$ C$_{3840}$, the SD of the radii for the molecules with defects stays at approximately 0.33 Å with increasing molecular size.

Figure 6 shows TB energies on a per atom basis of the fully optimized geometries for the molecules discussed above relative to an infinite sheet of graphite. The energies of these molecules are compared to those of $I_h$ fullerenes of similar size which represent global energetic minima. While the molecules with defects are slightly higher in energy than the $I_h$ molecules, their characteristic energy curve follows closely the $I_h$ energy curve, and approaches it with increasing molecular size. This result demonstrates that the molecules with defects are relatively stable structures that compare favorably with $I_h$ fullerenes for large systems. Initial attempts to find classical isomers of these molecules by carbon rearrangement to remove 7-membered rings were unsuccessful. Therefore, these molecules may or may not represent global energetic minima for their molecular size. Further studies will be required to determine the energetics of these molecules with relation to their isomers.

The results of our study provide a framework by which experimental observations of buckyonions can be understood in terms of $I_h$ fullerenes. Introduction of a minimal number of 5-7-5 defects via serial C$_2$ removal from 5-6 bonds results in a dramatic change in the shape of large $I_h$ fullerenes from faceted to round. This phenomenon can be attributed to a more even distribution of curvature strain on the surface of large fullerenes containing 5-7-5 defects rather than isolated pentagons. Our scheme of subsequent C$_2$ removal is energetically feasible and consistent with experimental observation of carbon evaporation during buckyonion formation. As shown in Figure 7, buckyonions composed of these molecules (6B) are much more consistent with experimental images than onions formed of polyhedral fullerenes.
The dramatic effect achieved by removal of only 24 atoms from the surface of these large $I_h$ fullerenes strongly suggests a very simple explanation for the observed sphericity of buckyonions and a closer relationship between the two carbon nanoparticles than previously expected.
