Purification and Properties of an ATPase from *Sulfolobus solfataricus*

Lawrence I. Hochstein* and Helga Stan-Lotter†

*Ames Research Center, Moffett Field, California 94035; and †The SETI Institute, Mountain View, California 94043

Received October 10, 1991, and in revised form January 17, 1992

A sulfite-activated ATPase isolated from *Sulfolobus solfataricus* had a relative molecular mass of 370,000. It was composed of three subunits whose relative molecular masses were 63,000, 48,000, and 24,000. The enzyme was inhibited by the vacuolar ATPase inhibitors nitrate and N-ethylmaleimide; 4-chloro-7-nitrobenzofurazan (NBD-CI) was also inhibitory. N-Ethylmaleimide was predominately bound to the largest subunit while NBD-CI was bound to both subunits. ATPase activity was inhibited by low concentrations of p-chloromercuriphenyl sulfonate and the inhibition was reversed by cysteine which suggested that thiol groups were essential for activity. While the ATPase from *S. solfataricus* shared several properties with the ATPase from *S. acidocaldarius* there were significant differences. The latter enzyme was activated by sulfate and chloride and was unaffected by N-ethylmaleimide, whereas the *S. solfataricus* ATPase was inhibited by these anions as well as N-ethylmaleimide. These differences as well as differences that occur in other vacuolar-like ATPases isolated from the methanogenic and the extremely halophilic bacteria suggest the existence of several types of archaeal ATPases, none of which have been demonstrated to synthesize ATP. © 1992 Academic Press, Inc.

F₀F₁ and vacuolar ATPases are membrane-bound proton translocating enzymes. The F₀F₁ ATPases are associated with bacterial cytoplasmic membranes, mitochondrial membranes, and thylakoids, where they function as ATP synthases. The vacuolar ATPases are located on the endomembranes of eukaryotic cells, where they hydrolyze ATP and generate gradients of protons that are subsequently used to transport solutes into intracellular vacuoles. These enzymes are also differentiated on the basis of the sensitivity of vacuolar ATPases to nitrate, NEM, and the antibiotic bafilomycin (1), agents that do not affect F₀F₁ ATPases. In addition, the enzymes' subunits differ with respect to their number and relative molecular masses (for recent reviews of F₀F₁ and vacuolar ATPases see Refs. (2) and (3), respectively). Although the amino acid sequences of the largest of the subunits of F₀F₁ and vacuolar ATPases suggest that they are related, the overall identity is low (4).

Archaeal ATPases are structurally unlike F₀F₁ ATPases. The catalytic portion consists of from two to five subunits (5–9) whose relative molecular masses are considerably higher than are those for the analogous subunits from F₀F₁ ATPases. In addition, there is no evidence for the presence of a membrane component equivalent to the F₀ moiety, although in the case of *Sulfolobus acidocaldarius* a low molecular mass DCCD-reactive proteolipid (10) exhibits considerable amino acid sequence homology with subunit c from F₀F₁ ATPases (11). The amino acid sequence of the α and β subunits of the ATPases from *Methanosarcina barkeri* (5) and *S. acidocaldarius* (12), and the two major subunits from the ATPase from *Halobacterium salinarium* (13) display considerable homology with sequences from subunits B and A, respectively, of vacuolar ATPases (14) which suggests that these enzymes are more closely related to vacuolar than to F₀F₁ ATPases. On the other hand, antiserum prepared against the β subunit of the ATPase from *S. acidocaldarius* cross-reacts with the β subunit from various F₀F₁ ATPases as well as subunit II from *H. salinarium* (9).

The ATPases from *H. salinarum* and *H. salinarium* (formerly designated *H. halobium*) are similar with respect to the relative molecular masses of the native enzymes

and their two major subunits (6, 15). Their sensitivity to nitrate and NEM suggests that they may be vacuolar ATPases (16). However, the situation in the halobacteria is complicated in that these ostensibly similar ATPases differ in several significant properties (17). An analogous situation exists in the case of *S. acidocaldarius*, where two ATPases have been described which possess very different properties (8, 18). We recently purified an ATPase from *S. solfataricus* whose several properties suggest that this enzyme is yet another type of Sulfolobus ATPase. We wish to report on these observations, suggest that they are consistent with the notion that there may be a multiplicity of Archaeal vacuolar-like ATPases, and emphasize that none has been demonstrated to synthesize ATP (i.e., act as an ATP synthase).

**MATERIALS AND METHODS**

**Growth and preparation of cell-free extracts.** Sulfolobus strain 982 was obtained from T. Langworthy and identified as *S. solfataricus* (N. Pace, personal communication). It was grown at 70°C in a medium consisting of the following additions (in grams per liter of deionized water): (NH₄)₂SO₄ (1.3), MgSO₄·7H₂O (0.25), CaCl₂·2H₂O (0.07), KH₂PO₄ (0.28), L-glutamic acid (0.5), and yeast extract (1.0). The pH was adjusted at room temperature to 3.2 with 5 N sulfuric acid. The medium was autoclaved for 15 min at 20 psi and after it had cooled, sterile water was added to bring the final volume to 2 liters of medium. The flask, which was placed in a heating mantle, had a condenser connected to one of the outlets; a gas dispersion tube fitted with a coarse glass-fritted cylinder was connected to the second outlet for the purposes of aerating the culture; and the third outlet was closed and used as a sampling port. The culture was vigorously aerated with sterile air which was first passed through a gas scrubber containing sterile water using a Cole Palmer Air Ladet vacuum/pressure pump operated at 3 psi. The cells were harvested after the culture entered the stationary phase (ca. 54 h) by centrifuging at 5900g for 30 min at 4°C. The cells were suspended in pH 7.1 Buffer A (20 mM Na–Hepes/10 mM MgCl₂/6 mM NaN₃/200 mM PMSE) to a buffer/cell ratio of 8 (vol/wt) and passed through a cold (ca. 4°C) French pressure cell operated at 12,000 psi. After centrifuging at 5900g for 30 min at 4°C, the resulting supernatant was washed with 245,000 g for 1 h at 4°C. The supernatant was decanted and designated the soluble fraction. The sediment was made up in Buffer A and designated the membrane fraction.

**Assays.** ATPase activity was determined at 86°C by following the release of P₃. The reaction mixture contained the following additions (in micromoles) in a total volume of 1 ml: Na–Hepes pH 6.6 buffer prepared at 86°C (50); MgCl₂ (6.25); ATP (12.5); and enzyme. The enzyme was incubated in the buffer for 2 min at 86°C before adding ATP (as the Mg-ATP complex). The reaction was terminated by the addition of 1 ml of cold (4°C) 10% trichloroacetic acid and any precipitate was removed by centrifugation at 3900g for 10 min at 4°C. When the protein concentration did not interfere with the *P₃* determination (which was the case with the UG and Seph 6B fractions) the reaction was terminated by adding 1 ml cold (4°C) water. Following the addition of water, the contents were kept at 4°C until assayed for *P₃*, which was determined by the method of LeBel et al. (19). The assay was linear for 15 min and up to the accumulation of 2 μmol of *P₃*. Protein was determined by the bicinchoninic acid method (20).

**Subunit labeling of NEM and NBD-CI**. The enzyme was labeled by adding 10 μl of the Seph 6B fraction (90 μg) to 190 μl of 50 mM Na–Hepes buffer (pH 7.2 at room temperature) that contained either 140 nmo1 N-[2,3-¹C]ethylmaleimide or 200 nmo1 of [U-¹C]NBD-CI. The mixtures were incubated for 30 min at room temperature and 2 min at 86°C. Excess NEM and NBD-CI were removed using the procedure described by Penefsky (21). The enzyme was subsequently dissociated by SDS and the location of radioactivity determined following SDS-PAGE.

**Polyacrylamide gel electrophoresis.** Analytical PAGE was performed at pH 8.9 using Tris glycine buffer and 5% gels according to the method of Davis (22). Proteins were detected by staining the gels overnight with Coomassie blue. ATPase activity was located on the gels as a calcium phosphate precipitate (23) in the following manner. The gels were suspended in 50 mM Na–Hepes buffer (pH 6.6 at room temperature) and incubated at room temperature for 15 min. The gels were subsequently transferred into tubes that had been preincubated at 86°C and contained 50 mM Na–Hepes buffer (pH 6.6 at 86°C) and 10 mM CaCl₂. Mg-ATP was added to a final concentration 12.5 mM and after about 15 min the enzyme was located by the appearance of a white band. A sample of the ATPase suitable for determining the subunit structure was obtained by electrophoresis of the Seph 6B fraction in several 5% gels. The enzyme was located by staining one gel for ATPase activity. Segments of the remaining gels corresponding to the location of the enzyme activity were macerated and extracted for 48 h at 4°C with Buffer B. The gel fragments were sedimented by centrifugation at 10,000g for 30 min at 4°C. The supernatant was decanted and used to determine the subunit structure of the enzyme. SDS–PAGE was carried out with 11% gels as described by Laemmli (24). Gels containing isotopes were soaked in Amplify and dried under reduced pressure and the radioactivity was detected on Kodak XAR 5 film by exposing the film at ~70°C.

**Determination of relative molecular mass.** The *M*₅ of the native enzyme was determined by gel filtration using a 1.5 × 84-cm UltroGel AcA34 column equilibrated in Buffer B. The following standards (with their *M*₅) were used: urease (480,000), catalase (232,000), aldolase (157,000), bovine serum albumin, dimer and monomer (134,000 and 67,000), and ovalbumin (45,000). The *M*₅ of the subunits was determined by SDS–PAGE using the Sigma SDS-70 low molecular weight kit standards.

**Materials.** Na–ATP, Na–ADP, P₃, and NBD-CI, and the SDS-70 low molecular weight kit were obtained from the Sigma Chemical Co. (St. Louis, MO). The Na–ADP contained 0.02% ATP which represented a quantity whose hydrolysis would not be detected given the conditions we employed to assay for *P₃* production. N-[2,3-¹C]Ethylmaleimide (7 mCi/mmol) was obtained from Amersham Corp. (Arlington Heights, IL) while [U-¹C]NBD-CI (109 mCi/mmol) was purchased from Research Products International Corp. (Mount Prospect, IL). Hepes was obtained from Cal Biochem (La Jolla, CA). Proteins were determined with reagents obtained from the Pierce Chemical Co. (Rockford, IL). The PD-10 desalting columns and Centricon 30 microconcentrators were obtained from Pharmacia Fine Chemicals (Piscataway, NJ) and the Amicon Corp. (Lexington, MA), respectively. UltroGel AcA34 was a product of LKB Instruments, Inc. (Gaithersburg, MD).

**RESULTS**

**Purification of the Enzyme**

ATPase activity was present in the membrane and cytoplasmic fractions. This distribution was directly related to the force used to disrupt the cells. In addition, storage of the membranes at 4°C resulted in the gradual appearance of soluble ATPase activity and was associated with the concomitant loss of membrane-bound ATPase activity. Preliminary experiments indicated the membrane and soluble activities were similar with respect to their response to anions, inhibitors, and pH and temperature optima (K. Meier and I. I. Hochstein, unpublished data). The enzyme in the soluble fraction was unstable and was immediately processed at least through the ammo-

The soluble fraction was adjusted to a protein concentration of 4 mg/ml with Buffer A and made 50% saturated with respect to ammonium sulfate. This mixture was stirred for 30 min at room temperature (ca. 22°C) and then centrifuged at 10,000g for 30 min at 22°C. The sediment was made up to a protein concentration of about 12 mg/ml with Buffer A and made 50% saturated with respect to ammonium sulfate. This mixture was stirred for 30 min at room temperature and then centrifuged at 10,000g for 30 min at 22°C. The sediment was made up to a protein concentration of about 12 mg/ml in Buffer A (AS fraction) and passed through an UltraGel AcA34 column (1.5 × 85 cm) equilibrated in pH 7.4 Buffer B (20 mM Hepes/6 mM NaNO₃). Those fractions that contained ATPase activity \( V_e/V_o = 1.42 \) were combined and designated the UG fraction. The UG fraction was made 18% with respect to \((NH_4)_2SO_4\) and applied to a Sepharose 6B column (1.6 × 29 cm) previously equilibrated in Buffer B that was also 18% with respect to \((NH_4)_2SO_4\). The column was washed with 100 ml of 18% \((NH_4)_2SO_4\)/Buffer B followed by a decreasing linear \((NH_4)_2SO_4\) gradient (18 to 6% ammonium sulfate in Buffer B over 200 ml). ATPase activity, which appeared between 13 and 11.5% \((NH_4)_2SO_4\), was combined, passed through a PD-10 desalting column, concentrated in an Centricon 30 microconcentrator, and designated as the Seph 6B fraction. The enzyme was stored at 4°C as it was unstable at -19°C and lost approximately 80% of its initial activity within 2 days at that temperature.

Table I summarizes a typical purification of the soluble ATPase starting with 3.5 g of cells. In this particular case, 75% of the total activity was associated with the soluble fraction. The soluble fraction also contained an active pyrophosphatase, the bulk of which remained soluble in 50% ammonium sulfate and which did not adsorb to Sepharose 6B in the presence of 18% ammonium sulfate. Following hydrophobic chromatography on Sepharose 6B and the removal of ammonium sulfate, the ATPase (i.e., the Seph 6B fraction) hydrolyzed 44 μmol of ATP/min/mg of protein which represented a 92-fold purification and a 21% recovery of the activity present in the soluble fraction. Once purified, the enzyme from S. solfataricus was extremely stable and could be stored at 4°C for at least 3 months with little loss of activity.

Several proteins were detected in the Seph 6B fraction by PAGE. Only one, which corresponded to the major constituent, exhibited in situ ATPase activity in the gels. To determine the subunit structure of the enzyme, the Seph 6B fraction was further “purified” by PAGE. For this experiment, 4.5 units of ATPase were subjected to PAGE and 3.2 units were subsequently recovered after extraction and concentration. The protein concentration following PAGE could not be determined as some component in the procedure interfered with the protein determination. The electrophoretically purified enzyme was composed of three subunits (Fig. 1a) whose \( M_r \) were 63,000, 48,000, and 24,000 (Fig. 1b). This compares with values of 65,000, 51,000, and 20,000 (9) and 69,000, 54,000, and 28,000 (8) for the subunits from the S. acidocaldarius ATPase. The \( M_r \) of the native enzyme was 370,000 which was consistent with the 3:3:1 subunit stoichiometry proposed for the S. acidocaldarius ATPase (18).

### Properties of the Enzyme

As shown in Fig. 2, ATP hydrolysis took place most rapidly at pH 6.6 when the enzyme was assayed at 86°C which was the temperature at which maximum ATPase activity occurred. There was no measurable activity at 30°C. The enzyme exhibited an absolute requirement for

![FIG. 1. Subunit structure of the S. solfataricus ATPase. The Seph 6B fraction (100 μg protein) was "purified" by PAGE and subsequently dissociated with SDS, and examined by SDS-PAGE. (a) Lane 1, molecular mass standards; lane 2, Sulfolobus ATPase. (b) Relative mobility \((R_f) = \log M_r\).]
Effect of Anions

ATPase activity was variously affected by anions (Fig. 3). Sulfite was stimulatory, with maximum activation taking place between 5 and 10 mM sulfite. Concentrations greater than 10 mM sulfite resulted in a progressive decrease in the extent of activation and eventual inhibition of ATP hydrolysis. This was an effect not previously reported for the other Sulfolobus ATPases. Nitrate also inhibited the enzyme. A 50% inhibition occurred in the presence of 8 mM nitrate, and 50 mM nitrate resulted in maximum inhibition (87%) of ATPase activity. The enzyme was inhibited by sulfate. A 50% inhibition was produced by 25 mM sulfate. The ATPase was inhibited by chloride although it was not too sensitive to that anion and was unaffected by 50 mM sodium bicarbonate. Replacing sodium with ammonium ion had no significant effect on sulfate or chloride inhibition (data not shown). This suggests that the anion inhibition was neither quantitatively nor qualitatively related to the cation.

Effect of Inhibitors

The *S. solfataricus* ATPase was inhibited by NEM (Fig. 4a), an alkylating reagent that reacts with sulphydryl groups, although the reagent will react with amino residues when conditions are mildly alkaline (25). Maximum inhibition occurred between 500 mM and 1 mM NEM (Fig. 4a). Divalent cation. Magnesium and manganese were equally effective, whereas calcium was ineffective. ATPase activity increased with the Mg/ATP ratio (ATP = 12.5 mM), reaching a maximum between 0.25 and 0.5; higher ratios resulted in a marked inhibition of ATPase activity. An apparent $K_m$ of 0.6 mM ATP was determined from Lineweaver-Burke plots (Mg/ATP = 0.5). The enzyme hydrolyzed the magnesium salts of ATP, GTP, and ITP at approximately the same rate which was about 5 and 50 times the rates observed with the magnesium salts of UTP and CTP, respectively. The Seph 6B fraction hydrolyzed Mg-ADP and MgP$_4$O$_7$ at 9 and <1% of the rate observed with Mg-ATP when assayed using conditions optimal for ATP hydrolysis. Since the Seph 6B fraction contained several minor components, the portion of ADP hydrolyzing activity associated with *Sulfolobus* was not certain. Mg-ADP also inhibited ATPase activity but determining a precise value for $K_m$ was complicated by the simultaneous hydrolysis of Mg-ADP. A 57% inhibition of ATPase activity was observed at ATP and ADP concentrations of 12.5 and 6.2 mM, respectively (Mg/nucleotides = 0.5). Plots of $1/V$ versus $1/S$ at different concentrations of ADP affected the slopes but not the intercepts indicating that Mg-ADP was a competitive inhibitor with respect to Mg-ATP.

**FIG. 2.** The effect of pH on ATPase activity. The Seph 6B fraction (2.5 µg protein) was assayed in the presence of the following buffers which were adjusted to the desired pH at 86°C: Mes (□), Heps (●), and Caps (○). 100% activity equals the production of 1.08 µmol P$_i$/10 min.

**FIG. 3.** Effect of anions on ATPase activity. The Seph 6B fraction (2.5 µg protein) was preincubated for 2 min at 86°C in the presence of the indicated concentrations of the sodium salts of sulfite (●), bicarbonate (□), chloride (○), sulfate (○), and nitrate (△) and subsequently assayed for ATPase activity. The results are reported as % of the activity observed in the absence of added anions which was assigned a value of 100% and was equal to the production of 1.15 µmol P$_i$/10 min.
4a). The enzyme was extremely sensitive to PCMS. As shown in Fig. 4b, 500 nM PCMS produced a 35% inhibition and enzyme activity was totally inhibited in the presence of 20 μM PCMS. Preincubating the enzyme for 10 min in the presence of 5 μM PCMS and subsequently for 2 min in the presence of 500 μM cysteine reduced the inhibition from 88 to 8%. The low concentrations of PCMS that inhibited the enzyme as well as the reversal of inhibition by cysteine were consistent with the involvement of thiols and by extension suggested that NEM also inhibited by reacting with thiol residues.

NBD-Cl inhibits F$_0$F$_1$ ATPases by reacting with a single tyrosinyl residue in the β subunit, and the inhibition can be reversed by thiols (26). In the case of vacuolar ATPases the mode of action is not known and the inhibitor binds to a number of subunits. The ATPase from _S. solfataricus_ was also inhibited by NBD-Cl. Preincubating the enzyme with 1 mM NBD-Cl for 15 min at 86°C inhibited ATPase activity 83% which was the maximum inhibition attained under these conditions (Fig. 5a). When the enzyme was preincubated at 86°C in the presence of 125 μM NBD-Cl, the inhibition, which was 25% after 15 min, was 77% after 2 h and appeared to continue to increase after that time (Fig. 5b). As also shown in Fig. 5b, the enzyme did not lose activity when incubated in buffer at 86°C for 120 min. As in the case of F$_0$F$_1$ ATPases (26), cysteine reversed NBD-Cl inhibition of the _Sulfolobus_ ATPase. In addition, cysteine activated the enzyme. These effects are shown in Table II. The extent of reversal was inversely related to the time the enzyme was exposed to NBD-Cl. Virtually all the ATPase activity was recovered when the enzyme was first incubated with 250 μM NBD-Cl for 15 min (which resulted in 52% inhibition) and then 1 mM cysteine for 10 min. When the enzyme was incubated for 3 h with 250 μM NBD-Cl (which resulted in a 96% inhibition) before the addition of cysteine, 42% of the activity was recovered. This suggested the existence of at least two NBD-Cl derivatives of the enzyme, only one of which was reversed by cysteine, and recalled the behavior of NBD-Cl with F$_0$F$_1$ ATPases (26). The presence of Mg-ATP did not protect the _Sulfolobus_ ATPase against NBD-Cl or NEM inhibition, which was unlike the ATPase from _H. saccharovorum_ (16).

When the ATPase was incubated with [¹⁴C]NEM so that the enzyme was maximally inhibited, the bulk of the radioactivity was associated with the 63,000-Da subunit with some radioactivity found with the 45,000- and 24,000-Da subunits (Fig. 6). When the enzyme was incubated in the presence of [¹⁴C]NBD-Cl, the inhibitor appeared to be equally distributed between the two largest subunits (Fig. 6). It is not clear if this distribution reflected nonspecific interactions due to the reactive nature of NBD-Cl (26) or if the high temperature during the assay exacerbated the reactivity and lack of specificity of NBD-
FIG. 5. Inhibition of ATPase activity by NBD-Cl. (a) The Seph 6B fraction (2.5 μg protein) was preincubated for 2 min at 86°C in the presence of the indicated concentrations of NBD-Cl and subsequently assayed for ATPase activity. (b) The effect of preincubation on inhibition. The enzyme was incubated at 86°C for the indicated times in the presence (●) and absence (○) of 125 μM NBD-Cl and assayed for residual ATPase activity as described under Materials and Methods. The results in both cases are reported as % of the activity observed in the absence of added NBD-Cl, where 100% equals the production of 880 nmol P10 min.

Cl and resulted in intersubunit migration of the inhibitor subsequent to initial binding.

ATPase activity was not affected by azide (10 mM), quercetin (200 mM), or vanadate (10 mM). DCCD (100 μM) was not inhibitory when incubated with the enzyme overnight at pH 6 at room temperature (22°C), conditions which inhibit the ATPase from H. saccharovorum and result in the binding of the inhibitor to subunit II (27).

DISCUSSION

The enzyme from S. solfataricus, like other archaeal ATPases, resembled vacuolar ATPases more than the F0F1 ATPase. The S. solfataricus ATPase was inhibited by NEM and nitrate, and the number and the relative molecular masses of its subunits was more in character with vacuolar ATPases. In addition, NEM was bound to the largest of the Sulfolobus ATPase subunits, as is true with the ATPase from H. saccharovorum (Sulzner et al., manuscript in preparation) and vacuolar ATPases, which in the latter case is proposed to be the catalytic subunit (28, 29). However, unlike the vacuolar and halobacterial ATPases, where the presence of ATP repressed NEM inhibition and decreased the incorporation of inhibitor, no substrate protection was observed in the case of the Sulfolobus enzyme.

The ATPase from S. solfataricus shared a number of properties with the S. acidocaldarius ATPase. The specific activities of the purified S. solfataricus and S. acidocaldarius (18) ATPases were similar; both ATPases were inhibited by similar concentrations of nitrate; and the relative molecular masses of the native enzymes and three of their subunits were in reasonable agreement. Recently, the enzyme from S. acidocaldarius was reported to contain a fourth subunit (9). Although we did not detect such a subunit, the composition of the S. solfataricus ATPase cannot be unequivocally established at this time. Proteolytic activity as well as the electrophoretic method used

![FIG. 6. [14C]NEM and [14C]NBD-Cl labeling of the S. solfataricus ATPase. The Seph 6B fraction was incubated with [14C]NEM or [14C]NBD-Cl and subsequently subjected to SDS-PAGE as described under Materials and Methods. Eight micrograms of protein was applied to each lane. to prepare the ATPase could have individually or collectively led to the loss of that subunit.

However, the Sulfolobus ATPases differ in ways to suggest they are not identical enzymes. Sulfate and chloride, which stimulate the ATPases from S. acidocaldarius, inhibit the S. solfataricus enzyme. Bicarbonate, which stimulates the enzyme from S. acidocaldarius, does not affect the ATPase from S. solfataricus. The Sulfolobus ATPases are also dissimilar with respect to their sensitivity to NEM and PCMS. The enzyme from the S. acidocaldarius is not significantly inhibited by NEM (8) and is considerably less sensitive to mercurials (18) than is the ATPase from S. solfataricus. The enzymes also differ with respect to their pH optima. In the absence of sulfite, the S. acidocaldarius ATPase exhibits acidic and alkaline maxima with a minimum at approximately pH 6.5. The addition of sulfite to the enzyme isolated by Lübben et al. (18) results in a single and relatively broad maximum (pH 5.5 to 7.0) with a 300% increase in enzyme activity. This stimulation is due to the increase in activity at the pH minimum. There is no stimulation at the alkaline pH maximum and only a 20% enhancement at the acidic pH maximum. The addition of sulfite to the ATPase described by Konishi et al. (8) enhances the activity at both optima so that the enzyme still exhibits two optima with the maximum stimulation of absolute activity occurring at the acidic maximum. The ATPase from S. solfataricus displayed a single pH optimum located between pH 6.5 and 7.2, regardless of the presence of sulfite, and the maximum sulfite stimulation was of the order of 60%. These and additional differences are summarized in Table III.

Differences also exist among ostensibly similar ATPases from other Archaea. The enzymes from H. saccharovorum and H. halobium have the same relative molecular masses as do their two major subunits, and both are equally sensitive to nitrate and NBD-CI. On the other hand, the enzymes differ with respect to their pH optima, detergent activation, and, most significantly, the effect of anions. The enzyme from H. saccharovorum is activated by chloride and detergent, whereas the enzyme from H. halobium exhibits very little activity in the presence of chloride, is activated by sulfite, sulfate, and citrate, and is unaffected by detergent. In addition, the enzyme from H. saccharovorum is unaffected by the nature of the cation, unlike the ATPase from H. halobium (15, 17). The ATPases isolated from methanogens also appear to differ. The enzyme from M. barkeri (30) is composed of two subunits (M, 62,000 and 49,000) and is activated by sulfite which causes a shift in the pH optimum to a more alkaline value. By way of contrast, the ATPase from Methanolobus tindarius is not activated by sulfite and is composed of four subunits whose relative molecular masses are 67,000, 52,000, 20,000, and <10,000 (31).

While archael ATPases appear similar, these differences suggest that they may be functionally different enzymes. It should be pointed out that, although ATP syn-

* S. solfataricus (this study).
+ S. acidocaldarius (8).
+ S. acidocaldarius (18).
NR, not reported.

thesis has been demonstrated in various Archaea (10, 31, 32), there is no direct evidence that such synthesis is caused by any of the archaeal ATPases which have been isolated to date. Whether Archaea synthesize ATP using an enzyme closely related to vacuolar ATPases, an F$_{0}$F$_{1}$ ATP synthase, or a third type of enzyme has yet to be established.

ACKNOWLEDGMENT

We acknowledge the technical assistance of Georgette George.
