Abstract. Electronic dimming of high-intensity discharge lamps offers control of photosynthetic photon flux (PPF) but is often characterized as causing significant spectral changes. Growth chambers with 400-W metal halide (MH) and high-pressure sodium (HPS) lamps were equipped with a dimmer system using silicon-controlled rectifiers (SCR) as high-speed switches. Phase control operation turned the line power off for some period of the alternating current cycle. At full power, the electrical input to HPS and MH lamps was 480 W (root mean squared) and could be decreased to 267 W and 428 W, respectively, before the arc was extinguished. Concomitant with this decrease in input power, PPF decreased by 60% in HPS and 50% in MH. The HPS lamp has characteristic spectral peaks at 589 and 595 nm. As power to the HPS lamps was decreased, the 589-nm peak remained constant while the 595-nm peak decreased, equaling the 589-nm peak at 345-W input, and the 589-nm peak was almost absent at 270-W input. The MH lamp has a broader spectral output but also has a peak at 589 nm and another smaller peak at 545 nm. As input power to the MH lamps decreased, the peak at 589 diminished to equal the 545-nm peak. As input power approached 428 W, the 589-nm peak shifted to 570 nm. While the spectrum changed as input power was decreased in the MH and HPS lamps, the phytochrome equilibrium ratio ($P_r : P_{in}$) remains unchanged for both lamp types.

Control of photosynthetic photon flux (PPF) in controlled-environment plant growth chambers often presents many obstacles (Bubenheim et al., 1988; Downs, 1975; McFarlane, 1978). As plant height increases during growth, lamp height must be adjusted, plants lowered, or filters placed between lamps and plants to maintain a specific flux at the top of the canopy. An alternative method to PPF control is electronic dimming of the lamps by reducing power input. Dimming of lamps offers several clear advantages; however, dimming systems are costly and approaches that alter arc characteristics of high-intensity discharge (HID) lamps result in spectral output. Use of silicon-controlled rectifiers (SCR) as high-speed switches to maintain arc integrity while decreasing power delivered to lamps represents a relatively new technology available for plant growth chambers.

Linear ballasts are traditionally used to drive HID lamps and are inherently less effective in maintaining lamp arc temperature than switching ballasts. The power input to any ballast is the sum of the power delivered to the lamp plus the power used by the ballast. The power of any electrical system is the product of the current input and voltage across the system. In a switching ballast, the amount of power delivered to a lamp is controlled by opening and closing solid-state switches. An ideal switch is 100% efficient, when closed it should allow current to flow with no voltage drop, and when open there should be no current. This concept is used in electronic switch-

ing ballasts by delivering power to lamps in small bursts. Since real electronic switches are not perfect, some deficiencies do exist and electronic ballasts perform at <100% efficiency. Although electronic switching ballasts are less than perfect, they still maintain a higher level of operational efficiency than linear ballasts, in which a large amount of power is dissipated within the ballast. Since the output of the linear ballast is constant, decreasing the power delivered to a lamp results in decreased operating arc temperature, thus possibly changing the spectral distribution. An electronic switching ballast should more effectively maintain arc temperature with short bursts at full power. The switching ballast should provide a more stable output than the linear ballast system.

In addition to the switching feature of the Macro HID dimmers (Macro Electronics Corp., Austin, Texas) used in this study, they have several other desirable features that are important characteristics of any effective dimming system. When the lamps are first energized, the dimmer automatically supplies full power, regardless of the dimming setting, allowing the arc tube to reach optimum operating temperature before responding to the dimming set point. Also, the system continuously monitors input line voltage and operates as a line voltage regulator by automatically compensating for changes in input line voltage.

The purposes of this study were to quantify the effectiveness of SCR electronic dimming in controlling PPF with metal halide (MH) and high-pressure sodium (HPS) HID lamps, to characterize any spectral changes associated with this method of dimming, and to assess the potential influence of any resulting spectral changes on plant physiology or morphology by monitoring phytochrome equilibrium ratios.

Materials and Methods

Growth chamber and lighting system. An Environmental Growth Chamber Corp. (Chagrin Falls, Ohio) model M-12 growth chamber was used for all testing. The chamber has interior dimensions of 1.2 m wide × 0.9 m deep

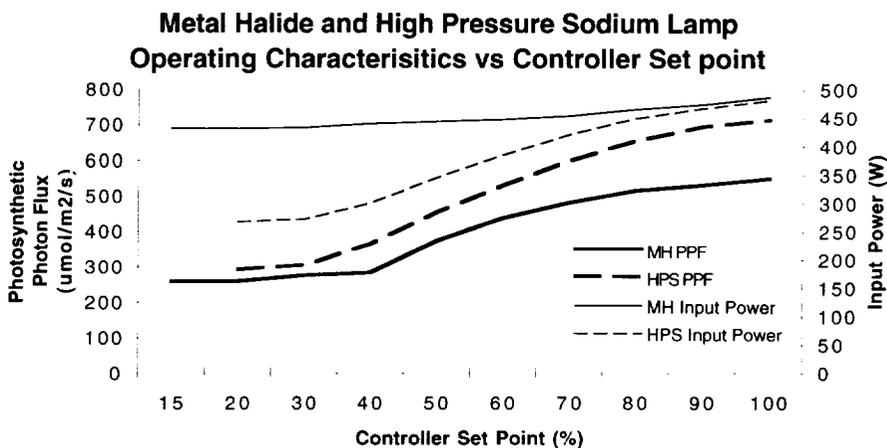

Fig. 1. Photosynthetic photon flux and input power to metal halide (MH) and high-pressure sodium (HPS) lamps as a function of variable voltage ballast controller set point.

× 1.2 m high; the interior walls of the chamber are polished aluminum. The custom lighting system consists of 12 HID, six 400-W HPS, and six 400-W MH lamps. The horizontally mounted lamps are alternately positioned in three rows of four to provide uniform irradiance from each lamp type, and each lamp is mounted in a polished aluminum reflector. The lamp bank assembly is suspended above a sheet of tempered glass with a 5-cm layer of water flowing over the glass to minimize nonphotosynthetic radiation entering the growth volume. The glass and water layer do not modify the radiation transmitted in the spectral range considered in this study (Bubenheim et al., 1988). The HPS and MH lamps can be powered independently or in combination.

HID dimming system. The HID dimmer operates by using SCRs as high-speed switches, in a phase control operation, to turn the alternating current (AC) line input power off during specified portions of the AC cycle; for full bright operation the on time is near to 100%. As off time is increased (duty cycle decreased), power to the ballast is lessened, thus less power is delivered to the HID arc tube, resulting in lower lamp output. When the SCR is off, it is fully off and no power is supplied to the ballast and lamp. If the switch remains off for too long, the arc of the HID lamp will extinguish; to extend the dimming range to provide low light levels, a separate circuit provides a small amount of current to the ballast and lamp while the SCRs are off for extended periods. We monitored line voltage to individual lamps using a multimeter capable of making true root mean squared (RMS) measurements.

Spectral measurements. The radiation environment was characterized over the 300- to 800-nm range at 5-nm steps with 30 samples per step using an EG&G Gamma Scientific (San Diego) spectroradiometer: model GS-4100 radiometer, NM-3DH monochromator, RS-10 standard lamp, D-46AQ photomultiplier and fiber optic tube with miniature cosine corrector as the receiver. The radiometer equipment was maintained outside of the growth chamber. The fiber optic cable entered the chamber and the distance from the receiver to the glass ceiling was maintained at 80 cm (distance to the lamps remained constant as well).

The spectral quality of HPS and MH output was characterized over the full dimmer range, 100% to arc extinguished, at 5% power input steps. The HPS and MH lamps were powered to the 100% setting and maintained there for 30 min. Following this warm-up period, the controlled setting was either reduced in 5% steps or the controller set points were randomly selected. The sequential down stepping and random controller setting approaches were repeated six times per lamp type, and lamps were allowed to equilibrate for 10 min at a set point before recording the spectral quality.

Because it was impractical to monitor the input voltage to each individual lamp simultaneously when the lamp bank was energized, we choose to report single lamp data where true RMS input wattage could be measured

accurately. We were able to monitor the input to two lamps simultaneously and were thus able to characterize the combined HPS and MH radiation environment. Variability among lamps of the same type was estimated by testing three individual lamps of each type over the full dimmer range, using the same fixture and reflector assembly. Data presented characterizing the variability in spectral quality, PPF, total energy output, and phytochrome equilibrium ratio observed among three lamps of the same type are for a 55% input controller set point, which corresponds to 365 and 445 W for the HPS and MH lamps, respectively.

Potential influence of any spectral changes associated with dimming of HPS and MH lamps was estimated by calculating the phytochrome equilibrium ratio ($P_r : P_w$) established in each radiation environment. The absorption coefficients used in these calculations were those published by Sager et al. (1986).

Results

No difference could be detected in spectral quality following random selection of the controller set point or sequentially stepping down from 100% to 20%; the data presented are a combination of both approaches. Data are

presented for single HPS and MH lamps. The same qualitative results were obtained with single lamps and lamp bank, only the absolute energy levels were greater with the lamp bank compared with a single lamp.

At full power the electrical input to HPS and MH lamps was 480 and 487 W (RMS), respectively, and was decreased to 267 and 428 W before the arc was extinguished (Fig. 1). Concomitant with this decrease in input power, PPF decreased by 60% in HPS and 50% in MH. In the HPS environment, PPF gradually decreased from 714 to 292 $\mu\text{mol}\cdot\text{m}^{-2}\cdot\text{s}^{-1}$ and from 551 to 259 $\mu\text{mol}\cdot\text{m}^{-2}\cdot\text{s}^{-1}$ with the MH lamps. The efficiency of the lamp/reflector configuration in this chamber provided an electrical efficiency (photosynthetic energy delivered to the growing plane/input wattage) of 30% with the HPS and 23% with the MH lamps. The delivered efficiency decreased to 22% and 12%, respectively, for HPS and MH as input wattage was decreased to the minimum.

The HPS lamp has characteristic spectral peaks at 589 and 595 nm (Fig. 2). At full input power of 480 W, the peak at 589 nm is 17% smaller than the 595 peak. As power to the HPS lamps was decreased, the 589-nm peak remained constant while the 595-nm peak de-

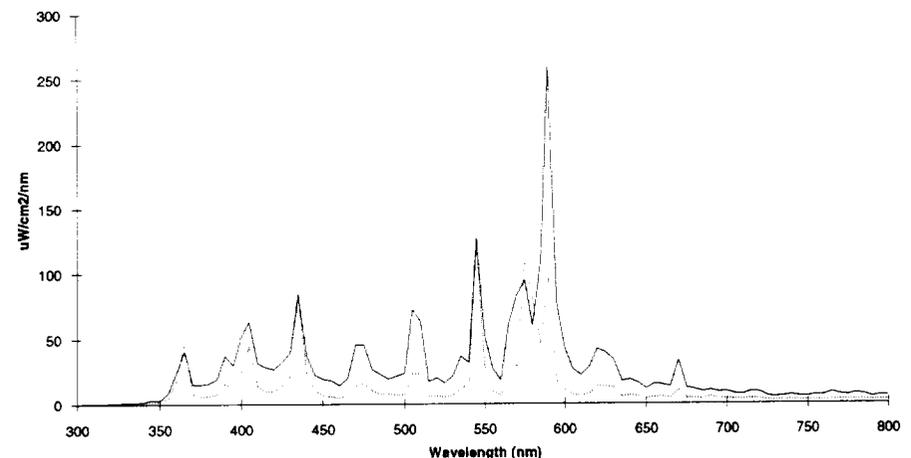

Fig. 3. Spectral quality resulting from operation of metal halide lamps at full input power (—, 480 W) or minimum power (-----, 428 W).

creased, equaling the 589-nm peak at 345-W input. The 595- and 589-nm peaks had almost completely collapsed at 270-W input, and a single dominant peak remained at 591 nm, the previous trough between the 589- and 595-nm peaks. Some energy was still present at 589- and 595-nm wavelength just before the arc extinguishing. The small peaks in the blue region remained and retained relative heights over the entire input power range. The phytochrome equilibrium ratio was calculated as 0.83 at full input power in the HPS environment. While there was a spectral shift associated with the decrease in input wattage, this shift occurred within a narrow waveband and resulted in only a slight decrease in the equilibrium ratio to 0.82.

The MH lamp has a broader spectral output but also has a peak at 589 nm and another, $\approx 50\%$ smaller, at 545 nm (Fig. 3). As observed with the HPS lamps, the primary peak dominance was diminished with a decrease in input wattage. The 589-nm peak in the MH environment was equal in height to the 545-nm peak at 442-W input. The 545-nm peak decreased very little as input power approached 428 W, but peak dominance was shifted from 589 to 545 nm. Two small peaks at shorter wavelengths, 360 and 440 nm, retained absolute peak height as the input power was decreased. While a spectral change occurred as input power was decreased in the MH lamps, the phytochrome equilibrium ratio decreased only slightly, from 0.79 at full power to 0.78 at the lowest power settings.

When HPS and MH lamps were operated simultaneously (Fig. 4), the characteristic peaks of the HPS dominate as a result of the greater efficiency of the HPS and thus greater characteristic energy flux. PPF resulting from the combined environment exceeded $1200 \mu\text{mol}\cdot\text{m}^{-2}\cdot\text{s}^{-1}$ and was reduced to $550 \mu\text{mol}\cdot\text{m}^{-2}\cdot\text{s}^{-1}$ at minimum power. The phytochrome equilibrium ratio established in the combined HPS and MH environment was 0.85 at full power and increased slightly, to 0.87, as the power was decreased. The unique spectral environment of the combined HPS and MH lamps resulted in a higher equilibrium ratio than that established under either individual lamp type. Differences between HPS and MH in electrical performance and quality shifts with decreasing input power also led to unique spectral environments and thus unique equilibrium ratios.

The variability among individual lamps ranged from 26% for MH to only 11% in the HPS for PPF and total energy flux (Table 1). Higher output of one MH lamp relative to the others tested resulted in the variability. The spectral output of individual lamps varied widely as well (Figs. 5 and 6). While there is variability in output and spectral quality of individual lamps, the phytochrome equilibrium ratio remains relatively unchanged. Morphological differences should not be expected to result from individual lamp spectral variability; however, test and selection of lamps based on similarity of energy output would significantly increase PPF and total radiant energy uniformity in the growth environment.

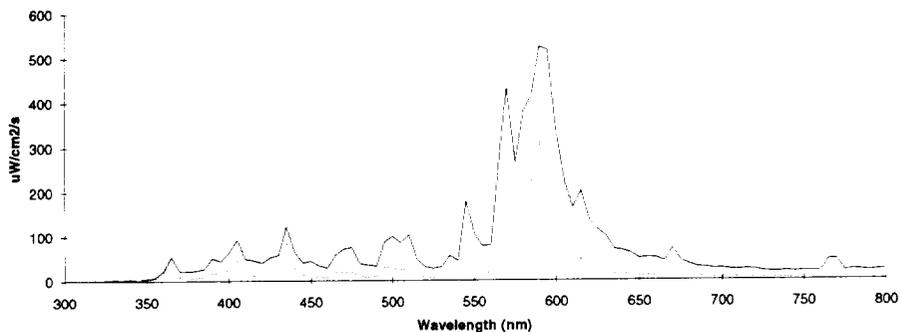

Fig. 4. Spectral quality resulting from simultaneous operation of metal halide (MH) and high-pressure sodium (HPS) lamps at full power (—) or minimum power (-----). Maximum and minimum input power was 480 and 428 W, respectively, for MH and 480 and 267 W for HPS.

Table 1. Photosynthetic photon flux (PPF), total energy flux, and phytochrome equilibrium ratio among three lamps of high-pressure sodium (HPS) and metal halide (MH). All lamps were 400 W and were operated at an input power set point of 55%, which corresponds with 365 and 445 W for the HPS and MH lamps.

Lamp type and sample	PPF ($\mu\text{mol}\cdot\text{m}^{-2}\cdot\text{s}^{-1}$)	Total energy flux ($\text{mW}\cdot\text{cm}^{-2}$)	Phytochrome equilibrium ratio ($P_{fr} : P_{ox}$)
MH

Conclusions

Electronic dimming of HPS and MH high-intensity discharge lamps using silicon rectifiers is an effective method for controlling PPF. Some spectral changes resulted from decreased input power to HPS and MH lamps; however, these changes were consistently limited to shifts in relative magnitude of the major peaks. We estimate the physiological and morphological consequences of these spectral shifts to be small, because the phytochrome equilib-

rium ratio remained relatively unchanged in each of the environments tested. It appears that PPF can be reduced by $>50\%$ using electronic dimming of HPS and MH lamps without significantly altering the spectral quality.
