ABSTRACT

Imperfections in gear tooth geometry often result from errors in the manufacturing process or excessive material wear during operation. Such faults in the gear tooth geometry can result in large vibrations in the transmission system, and, in some cases, may lead to early failure of the gear transmission system. This report presents the study of the effects of imperfection in gear tooth geometry on the dynamic characteristics of a gear transmission system. The faults in the gear tooth geometry are modeled numerically as the deviation of the tooth profile from its original involute geometry. The changes in gear mesh stiffness due to various profile and pattern variations are evaluated numerically. The resulting changes in the mesh stiffness are incorporated into a computer code to simulate the dynamics of the gear transmission system. A parametric study is performed to examine the sensitivity of gear tooth geometry imperfections on the vibration of a gear transmission system. The parameters vary in this study consist of the magnitude of the imperfection, the pattern of the profile variation, and the total number of teeth affected. Numerical results from the dynamic simulations are examined in both the time and the frequency domains. A joint time-frequency analysis procedure using the Wigner-Ville Distribution is also introduced to identify the location of the damaged tooth from the vibration signature. Numerical simulations of the system dynamics with gear faults were compared to experimental results. An optimal tracker was introduced to quantify the level of damage in the gear mesh system. Conclusions are drawn from the results of this numerical study.

CHAPTER 1

INTRODUCTION

Gearing, one of the most universally used machine elements, is applied in mechanical systems of every size and description: from the tiny pinions in a watch or a computer system to the high-speed, heavily-loaded reduction gears of an aircraft gas turbine. In the last two decades, the use of gear transmissions in both defense and commercial applications has substantially increased. With the demand for higher power and performance, premature failures in transmissions often result in financial losses, and sometimes even lead to catastrophic consequences. In the aerospace industry, where both weight-to-load factor and efficiency are pushed to their design limits, one of the major concerns is fatigue failures in rotorcraft gear transmission systems. Such failures are often a result of excessive gear tooth wear and tooth crack formation. Presently, the prevention and management of premature equipment failures has become a vital part of the maintenance program.

Current on-board condition monitoring systems for gas-turbine engine systems often fail to provide sufficient time between warning and failure such that safety procedures can be implemented. On the other hand, inaccurate interpretation of operational conditions may result in false alarms and unnecessary repairs and downtime. The early detection of incipient failure in a mechanical system is of great practical importance as it permits scheduled inspections without costly shutdowns, along with indication of urgency and location for repair before any catastrophic failure.

Presently, a considerable amount of work in machine life prediction has been carried out using machine reliability and design life approaches[1,2]. However, most of this work is based on statistical predictions developed by Lundberg and Palmgren[3] without considering the conditions of machine components during various phases of their lifespan. Besides the work reported in recent years by the Mechanical Failure Prevention Group(MFPG)[4-6], very little has been cited in the literature concerning condition-based failure prediction.
The increasing requirements for long life and safe operation in mechanical systems call for the development of an accurate machine fault identification and failure prognostication system which is capable of on-line machine health monitoring as well as machine life prediction. One of the advanced fault identification procedures used in rotorcraft mechanical systems is the signature analysis of machine vibration/acoustic signals\[7 - 9\]. The acquired machine vibration/acoustic signature is compared to a data bank of standard healthy machine operation signatures to pinpoint the abnormalities of the input signal. This procedure does not require a shut down of the rotating machinery, and can be used as an in-flight diagnostic and trend monitoring device.

In order to develop an accurate machine fault identification and failure prognostication system, it is very important to understand the dynamics of a gear transmission system under a variety of fault conditions, as well as under nominal conditions. This study deals only with the basic knowledge in fault identification of gear component and the dynamic modelling of a gear transmission system under the effects of gear tooth geometry imperfection.

The major objective of the research presented herein is the development of a numerical model to predict the vibration in a gear transmission system due to gear tooth imperfection or damage. The imperfection/damage of the gear tooth geometry is modeled numerically as the deviation of tooth profile from its original geometry. To simulate gear failures, a computer code developed at NASA Lewis Research Center\[10\] was modified to simulate various types of gear mesh conditions. The changes in mesh stiffness due to the effects of tooth wear can be represented by using a tooth profile modification procedure. The resulting changes in mesh stiffness are incorporated into the dynamic simulation of the gear transmission system.

In simulating the vibration of the transmission system, the equations of motion are established individually for each rotor-gear-bearing system. These localized changes in the gear mesh stiffness are incorporated into each gear-rotor model during the dynamic simulation \[11-13\]. The dynamics of each gear-rotor system are coupled with each other through the gear mesh interacting forces and the bearing supporting forces. The global vibrations of the system are evaluated by solving the set of coupled transient dynamics
equations of all the rotor systems simultaneously including the vibration of the casing. In order to minimize the computational effort, the number of degrees-of-freedom of the system are reduced by using a modal synthesis procedure[ 11,12 ].

Results from the model were examined using a joint time-frequency analysis method. This approach was chosen because the joint time-frequency analysis will provide an instantaneous frequency spectrum of the system at every instant of the revolution of the pinion while the traditional frequency analysis can only provide the average vibration spectrum of the signal. In other words, the time-changing spectral density from the joint time-frequency spectra will provide vital information concerning the frequency distribution concentrated at a particular instant. The Wigner-Ville Distribution (WVD) [ 14-16 ] was chosen for the joint-time frequency analysis. Considerable success has been achieved in applying the WVD to gear transmission systems [ 17,18 ] to recognize faults at various locations of the gear.

In addition, experimental results obtained from a gear failure test rig at NASA Lewis Research Center were also used to experimentally validated the identification procedure using the WVD as well as to verify the numerical simulations. A technique for quantifying the damage in a gear mesh using an optimal tracker was also developed, and results obtained using the optimal tracker were compared with those from the experimental studies.

Based on results of this study, general conclusions are made concerning the effects of local damage on the global damage of the gear transmission system. This study applied the above discussed methodology on a variety of damaged gear models. The numerical model used to simulate the dynamics of a gear transmission system with gear tooth geometry imperfections was successfully developed. In addition, considerable success was achieved in generating a comprehensive database of the vibration signal due to various kinds of gear tooth geometry imperfection patterns a in gear transmission system. Some limited success was achieved in quantifying the damage using an optimal tracker. Using the developed analytical/numerical model, a gear more extensive fault/damage database can be developed for machine fault identification and failure prognostication research.
CHAPTER 2

THE EFFECTS OF GEAR TOOTH IMPERFECTION
ON GEAR MESH STIFFNESS

2.1 Objective

The magnitude variation in the tooth mesh stiffness can affect gear mesh dynamics and loading significantly. The first step in determining the effects of gear tooth imperfections on gear mesh dynamics is to determine the relationship between gear tooth imperfections and the resulting change to gear mesh stiffness.

The objective of this chapter is to develop a relationship describing the effects of gear tooth imperfections on the static behavior of a gear system, with an emphasis on the gear mesh stiffness. The method which calculates the tooth mesh stiffness of a gear system is presented by Richardson [19]. The imperfection of a gear tooth is modeled numerically as the deviation of the tooth profile from its designed geometry. The changes in gear mesh stiffness due to various profile changes and imperfection patterns are evaluated numerically. A computer code developed at NASA Lewis Research Center[10] was modified to simulate various types of gear mesh conditions.

2.2 Gear Kinematic Properties

The ideal kinematic requirement for gear action is constant speed ratio. That is, the angular velocity of the driven gear should be a constant multiple of the angular velocity of the driving gear. Two curves that possess the property of constant speed ratio when operated as contacting tooth surfaces are called conjugate curves. From the infinite
variety of possible conjugate curves, the involute has been almost universally accepted for use in gearing. An involute curve is generated by the end of a line that is unwound from the circumference of a circle called the base circle.

Figure 1 shows two gear teeth in contact. Point L on gear 2 is in contact with point M on gear 1. At this point of contact, the two tooth surfaces must be tangent to each other and consequently must have a common normal $W_1W_2$ passing through the point of contact which intersects the line of centers $C_1C_2$ at the instant center $P$, called the *pitch point*. Since ideal gears are assumed rigid, the velocities of $L$ and $M$ along the normal $W_1W_2$ must be equal. The velocities of $L$ and $M$ perpendicular to the normal sliding or relative velocity of the tooth surfaces.

$$V_{12} = w_2 \overline{C_2W_2} ; \quad V_{11} = w_1 \overline{C_1W_1} \quad (2.1)$$

where $w_1$ and $w_2$ are the angular velocities of gears 1 and 2, respectively. Hence, by similar triangles

$$\frac{w_1}{w_2} = \frac{R_2}{R_1} \quad (2.2)$$

This equation is frequently used to define the law of gearing, which states that the pitch point must remain fixed on the line of centers. This means that all the lines of action for every instantaneous point of contact must pass through the pitch point. Consequently, ideal gears can be represented kinematically by two imaginary cylinders of radii $R_1$ and $R_2$, called *pitch cylinders, which roll on each other without slipping*. 
Figure 1. Involute gear geometry
If no friction is present between the mating gear profiles, then the resultant force transmitted at the contact point L must lie along the common normal. For this reason the common normal is called the pressure line, and the angle between the normal and a line perpendicular to the line of centers C1C2 is called the pressure angle θ. The locus formed by all points of contact as the gears rotate is known as the path of contact.

In order to maintain continuous conjugate action, a series of conjugate curves are spaced uniformly around the circumference of a gear. The separation of these curves, measured along the pitch circle, is called the circular pitch

\[ P_c = \frac{2\pi R}{i} \]  

(2.3)

where i is the number of teeth, and R is the pitch-circle radius. The diametrical pitch is defined as the number of teeth on the gear per inch of pitch diameter, as indicated in the following equation;

\[ P = \frac{i}{2R} \]  

(2.4)

The relationship between circular pitch and diametral pitch is as follows:

\[ P_c P = \pi \]  

(2.5)

In an involute gear, the spacing of successive involutes along the pressure line or line of action is known as the normal pitch, and is related to the circular pitch defined by Equation (2.3) in the following way

\[ P_n = P_c \cos \theta \]  

(2.6)

The contact-ratio is defined as the path of contact divided by the normal pitch, and is a measure of the average number of tooth-pairs in contact. To provide continuous action the contact ratio must be greater than one, and for most power transmission
gearing, the value of this quantity lies between the values of one and two. In some instances, the contact ratio can be as high as four.

The radial length of the teeth beyond the pitch circle is called the addendum distance, and the radial depth of the teeth below the pitch circle is called the dedendum distance. By trade association standards, these distances are specified as constant multiples of the circular pitch.

The location in the gear mesh of the contact point between mating teeth can be specified conveniently by the distance, s, between the pitch point and the contact point, measured along the line of action.

When load is being transmitted through the gear mesh, the load is carried either by one pair of teeth alone or jointly by two or more pairs of teeth depending on the value of the contact ratio. It is assumed here that the contact ratio is between one and two. As the gears rotate, the load is transferred from teeth that are in mesh to succeeding teeth that are moving into mesh. Similarly, teeth moving out of mesh relinquish load as they leave contact.

2.3. Load-Deflection Properties of a Gear Mesh

2.3.1 Definition of Spring-Stiffness of Gear Mesh

The ideal curves that are used to form gear teeth are designed to produce a constant speed ratio. That is, the gears behave like two imaginary pitch cylinders which roll without slipping.
In actual gears, the materials employed cannot be absolutely rigid; consequently, the gear-teeth will deflect due to the transmitted loads, which will cause the ideal pitch circles to slip. Thus a deviation from ideal kinematic operation occurs.

For example, in Figure 2, gear 2 is fixed, by definition its pitch circle is also fixed. Now consider a torque $\tau_1$ to be applied to the mating gear 1. This torque on gear 1 must be balanced, for static operation, by the moment of the resultant force $F$, which, in the absence of friction, acts along the pressure line.

$$\tau_1 = F \cos \theta R_1$$  \hspace{1cm} (2.7)

or in terms of $T$, the component of $W$ which acts tangentially to the pitch circle,

$$\tau_1 = T R_1$$  \hspace{1cm} (2.8)

When friction is present, or contact between mating teeth lies off the pressure line, $W$ and $T$ in Equations (2.7) and (2.8) no longer represent tooth loads exactly, but are still convenient ways of expressing the input torque $\tau_1$.

The spring stiffness of the gear mesh is defined as the amount of tangential load $T$, computed from Equation (2.8), to produce one unit of pitch-circle slip, $\delta$, as shown in Figure 2

$$K_p = \frac{T}{\delta}$$  \hspace{1cm} (2.9)
Figure 2 (a) Pitch - Circle Slip
Figure 2 Definition of Gear-Mesh Spring-Stiffness

(b) Loaded Gear Teeth

(c) Applied Loads
This definition can be equally well stated as the amount of load $W$ acting along the pressure line, required to produce one unit of relative displacement ($s_r$) between gears, measured along the pressure line

$$k = \frac{F}{s_r}$$  \hspace{1cm} (2.10)

Where

$$F \cos \theta = T$$  \hspace{1cm} (2.11)

and

$$s_r = \delta \cos \theta$$  \hspace{1cm} (2.12)

These two spring stiffness are related by virtue of Equations (2.11) and (2.12)

$$k = \frac{T}{\delta (\cos^2 \theta)} = \frac{K_p}{\cos^2 \theta}$$  \hspace{1cm} (2.13)

2.3.2 Compliance for a Single Pair of Teeth

The determination of the compliance of gear teeth is considerably difficult because it is an integral function of the entire loaded tooth. In addition, because of the stubbiness of the teeth, the foundation and shear effects are important. Cornell’s method [20] parallels, to a great extent, Weber’s work[21], however Cornell uses O’Donnell’s foundation factors [22,23]. The total compliance or flexibility of a gear tooth at the point of load, $y_T$, is made up of three deflections:

1. The basic deflection of the tooth as a cantilever beam, $y_B$;
2. The deflection of the tooth caused by the fillet and foundation flexibility [22], $y_F$;
3. The local deflection caused by the contact and compression between the two teeth, $y_L$. 
When two gear teeth are in contact, the total compliance is their combined deflection per unit of load at the contact position or

\[ C = (y_{T1} + y_{T2})/L = [(y_{B1} + y_{B2}) + (y_{F1} + y_{F2}) + y_L)]/L \]  \hspace{1cm} (2.14)

where L is the applied load, and the deflections y are in the direction of the load. The methods to calculate the three types of deflections in equation (2.14) are given below.

2.3.2.1 The Basic Deflection of the Tooth as a Cantilever Beam

When a load L is applied to the surface of a gear tooth, a deflection of the tooth occurs in the direction of the load. Suppose that the tooth is rigid near the point of loading. Then deflections of the tooth will still occur due to each of the following effects.

1. Bending of the tooth in the manner of a cantilever beam.
2. Direct compression of the tooth due to the radial component of the load (N)
3. Direct shearing of the tooth due to the tangential component of the load (T).

The deflection and, therefore, compliance of a gear tooth over its beam portion is easily obtained using elementary strength of materials. Referring to Figure 3(a), the total of the bending and shear deflection in the direction of and at the point of application of the tooth load L, which is at radius R_L or position S along the line of action, can be expressed in integral form as

\[ y_b = \frac{L \cos^2 \phi L}{E} \int_0^\xi \left\{ \frac{\eta}{I} d\eta + \frac{2.40(1 + \mu) + Tan^2 \phi L}{A} \right\} dz \]  \hspace{1cm} (2.15)

where I is the section modulus of the tooth, and using the relationship of

\[ \xi = x \hspace{0.5cm} \text{or} \hspace{0.5cm} \eta = z; \hspace{0.5cm} \eta = (\bar{l} - \xi) = z = (\bar{l} - x) \]  \hspace{1cm} (2.16)
Figure 3. Beam compliance of a gear tooth
and a value of 1.2 has been assumed for the shear factor based on a rectangular tooth;

\[ G = \frac{E}{2(1 + \mu)} \quad (2.17) \]

and A is the cross-sectional area as a function of x or z. The deflection of the basic tooth can also be defined in a summation expression rather than integral form, see Figure 3(b), In this case the tooth beam deflection at and in the direction of the load is

\[ y_b = \frac{L \cos^2 \phi_L}{E} \sum_{i=1}^{4} \delta_i \left\{ \left( I_i^2 - l_i \delta_i + \frac{1}{3} \delta_i^2 \right) \frac{1}{\bar{I}_i} + \frac{2A(1 + \mu) + Tan^2 \phi_L}{\bar{A}_i} \right\} \quad (2.18) \]

Where

\[ \frac{1}{\bar{I}_i} = \left( \frac{1}{I_i} + \frac{1}{I_{i+1}} \right) / 2 \quad (2.19) \]

and

\[ \frac{1}{\bar{A}_i} = \left( \frac{1}{A_i} + \frac{1}{A_{i+1}} \right) / 2 \quad (2.20) \]

Using these inverse forms for the values of \( \bar{I}_i \) and \( \bar{A}_i \) improves the accuracy for a small number of elements. In equation (2.18)

\[ l_i = (\bar{I} - x_i) \quad (2.21) \]

and

\[ \delta_i = (x_{i+1} - x_i) \quad (2.22) \]

Both approaches for beam flexibility assume a narrow tooth width, W. For wide teeth where \( W/h_p > 5 \), the flexibility is decreased by the antielastic effect, so that the values of I in equations (2.15) and (2.18) should be divided by \( (1-\mu^2) \).
2.3.2.2 The Deflection of the Tooth Caused by the Fillet and Foundation Flexibility

Because of the fillet and the flexibility of the material to which the tooth is attached, additional deflection will occur at the load; see references [21-23]. This fillet and foundation deflection in the direction of the load, \( y_F \), is a function of the fillet geometry and the load position and direction, and is determined by the effective fillet length or angle \( \gamma_F \) for which the maximum deflection or work occurs at the load.

Based on Figure 4, O'Donnell [22, 23] shows that the deflection at and in the direction of the tooth load due to the foundation effects, \( y_{FF} \), for plane stress is

\[
y_{FF} = \frac{L \cos^2 \phi_L}{WE} \left[ \frac{16.67}{\pi} \left( \frac{1_F}{h_F} \right)^2 + 2 \left(1 - \mu\right) \left( \frac{1_F}{h_F} \right) + 1.534 \left( \frac{1 + \frac{\tan^2 \phi_L}{2.4(1 + \mu)}}{h_F} \right) \right]
\]

For wide teeth the expression for plane strain is used or

\[
y_{FF} = \frac{L \cos^2 \phi_L}{WE} \left[ \frac{16.67}{\pi} \left( \frac{1_F}{h_F} \right)^2 + 2 \left(1 - \mu - 2\mu^2 \right) \left( \frac{1_F}{h_F} \right) + 1.534 \left( \frac{1 + \frac{\tan^2 \phi_L}{2.4(1 + \mu)}}{h_F} \right) \right]
\]

The O'Donnell coefficients in equations (2.23) and (2.24) differ slightly from those given by Weber[21]. The first term in the brackets is the deflection at \( L \) due to the rotation caused by the moment at \( h_F \). The second term is the sum of the deflections at \( L \) due to the displacement at \( h_F \) caused by the moment at \( h_F \) and the rotation at \( h_F \) caused by the shear force at \( h_F \). The first part of the third term is the displacement at \( L \) due to the shear force at \( h_F \) based on the assumption that the effective depth for determining this deflection is \( 2^{1/2} \) times the tooth thickness [21]. The second part of the third term is the deflection at
L due to the normal component of the load assuming the same relationship holds as indicated by the beam deflection equation; see equations (2.15) and (2.18).

Referring to Figure 4, the deflection at and in the direction of the load due to the flexibility of the fillet and foundation, $y_F$, the shaded region, is obtained from the summation of the fillet beam deflection, $y_{FB}$, using equations (2.15) and (2.18), and the foundation deflection $y_{FF}$, using equation (2.23) or (2.24), i.e.,

$$y_F = y_{FF} + y_{FB} \quad (2.25)$$

where

$$l_F = \bar{l} + r(Sin\gamma_F - Sin\bar{\gamma})$$

$$h_F = \bar{h} + 2r(Cos\bar{\gamma} - Cos\gamma_F)$$

$$l_i = \bar{l} + r(Sin\gamma_i - Sin\bar{\gamma})$$

$$h_i = \bar{h} + 2r(Cos\bar{\gamma} - Cos\gamma_i) \quad (2.26)$$

The value of $\gamma_F$ is the one that maximizes the value of $y_F$ or $y_T$, which can easily be done as one integrates or sums up the deflection of the tooth starting at the beginning of the fillet or at the load position.

### 2.3.2.3 The Local Deflection Caused by Compression of the Tooth Surfaces

The local compliance, $y_L$, consists of the Hertz or line contact deflection plus the compression of each tooth between the point of contact and the tooth centerline. Figure 15 gives the nomenclature for the parameters that determine the local deformation. There are several approaches to calculate the local compliance. All of the expressions for the local deformation are nonlinear with load because of the Hertz half contact width $b$.

Here, the closed form approach developed by Weber[21] was adopted.
Weber in reference [21] developed an expression specifically for the local deformation of two gear teeth, based on Hertz's work on deformation between cylinders. In order to obtain a closed form solution, he assumed small deformations so that just the first two terms of the binomial expansion of the deformation needed to be used - i.e.,

Figure 4. Fillet and foundation compliance of a gear tooth
Figure 5. Nomenclature for local compliance

\[
\phi'_{L1} = \phi_{L1} - \alpha_1 \\
\phi'_{L2} = \phi_{L2} - \alpha_2 \\
\phi_{L1} = \phi_{L2} = \phi_L
\]

\[
r_1 = R_1 \sin \phi_L = R_{B1} \tan \phi_L \\
r_2 = R_2 \sin \phi_L = R_{B2} \tan \phi_L \\
b = \text{Half Hertz Contact Width} \\
h_1 = \frac{1}{2} h_{L1} / \cos \phi'_{L1} \\
h_2 = \frac{1}{2} h_{L2} / \cos \phi'_{L2}
\]

\[
\gamma_L = \frac{2L}{\pi W} \left[ \left( \frac{1 - \mu_1^2}{E_1} \right) \ln \frac{2h_1}{b} - \left( \frac{\mu_1}{2(1 - \mu_1)} \right) \right] \\
+ \left( \frac{1 - \mu_2^2}{E_2} \right) \ln \frac{2h_2}{b} - \left( \frac{\mu_2}{2(1 - \mu_2)} \right) \right]
\]

where
\[ b = \left( \frac{4L}{\pi W} \left[ \left( \frac{1 - \mu^2_1}{E_1} \right) + \left( \frac{1 - \mu^2_2}{E_2} \right) \right] \left[ \frac{1}{r_1} + \frac{1}{r_2} \right] \right)^{1/2} \]  \hspace{1cm} (2.28)

If \( E_1 = E_2 \) and \( \mu_1 = \mu_2 \), equation (2.27) reduces to

\[ y_L = \frac{4(1 - \mu^2)}{\pi E} \frac{L}{W} \left[ \frac{1}{\ln \left( 2\sqrt{\frac{h_t h_r}{b}} \right)} - \left( \frac{\mu}{2(1 - \mu)} \right) \right] \]  \hspace{1cm} (2.29)

The overall compliance, \( C \), of the tooth pair is obtained by adding the local gear tooth compliance defined by equation (2.27) with the gross tooth compliance for the two gear teeth

( \( y_B + y_F \) / L given by equations (2.15) or (2.18) and (2.25); see equation (2.14).

2.3.3 Load - Deflection Relationship of a Gear Mesh

When the total compliance for a single pair of teeth is known for all points of contact along the pressure line, computation of the gear-mesh compliance can be carried out. Two cases are possible:

1. Only one pair of teeth is in contact; then the mesh compliance is equal to the single-tooth pair compliance. This is normally the case when contact is near the pitch point.

2. More than one pair of teeth is in contact. Successive pairs of teeth are spaced along the line of action by one normal pitch. Consequently, the compliance curves for successive tooth -pairs also can be spaced along the line of action by the same amount.

For simplicity, the real gear - action is modeled as shown in Figure 6 which represents engagement and disengagement of the various pairs of teeth. The gear action can be represented by the movement of a cam underneath successive pairs of teeth. This
cam is shown in Figure 6 during its passage underneath tooth-pairs n, n-1 and n+1; however, after leaving these pairs, it will continue on, bringing other tooth pairs into contact in succession. Point P on the cam surface corresponds to pitch-point contact, and when any tooth-spring is contacting the cam at P, that tooth-pair is in contact at the pitch-point in the real gear system. Tooth-springs in the model are spaced in the gear by an interval of one normal pitch, just as the actual tooth-pairs are spaced in the gear system. The distance AC on the cam is flat, and is equal to the ideal path of contact. Any tooth-pair start engagement at point E and is in full engagement at point A and remain in contact until point C is reached, then starts disengagement, until point D is reached.

The load W is the total load transmitted through the mesh, and \( s_r \) is the relative motion between mating gears, measured along the pressure line. The relative motion is resisted by the tooth-pair stiffness, \( k_n \), \( k_{n+1} \), \( k_{n-1} \), etc., depending on the number of teeth in contact.

For example, tooth-pairs n and n+1 are in contact at the position shown in Figure 6, the compliance for the mesh at this position is given by the resultant compliance of the
Fig. 6 Model of Gear Action
tooth-springs n and n+1. Since the load L is shared between the two springs, the total compliance is the parallel-combination of the individual compliance.

\[ \frac{1}{C_{\text{total}}} = \frac{1}{C_n} + \frac{1}{C_{n+1}} \]  

(2.30)

or

\[ C_{\text{total}} = \frac{C_n C_{n+1}}{C_n + C_{n+1}} \]  

(2.31)

This result is easily generalized to the combined compliance for n pairs of teeth.

\[ C_n = \frac{\prod_{l=1}^{n} C_l}{\sum_{r=1}^{n} \prod_{k=1}^{r} C_k \prod_{m=r+1}^{n} C_m} \]  

(2.32)

where each C refers to the component compliance of a given tooth-pair at a certain location along the pressure line.

2.4. Model of Imperfection in Gear Tooth

To simulate gear failures, a computer code developed at NASA Lewis Research Center[10] was modified to simulate various types of gear tooth imperfection. The imperfection of the gear tooth was modeled by using a tooth profile modification procedure that simulates changes in gear tooth surface profile. The tooth profile modification is represented by their respective cams in Figure 6. The cams representing the tooth profile modifications have the form

\[ C_e (S - S_e)^x \quad \text{and} \quad C_d (-S_d - S)^x \]  

respectively  

(2.33)

where x is an integer. Typical gear tooth profile modifications were found to be represented quite well by simply using a cam form with x = 2; see Figure 6.
Hence the imperfection of the tooth can be simulated by engagement and disengagement tooth profile modifications $\varepsilon_d$ and $\varepsilon_e$, which represent the deviation of the profile from the ideal tooth geometry, and are assumed to be a square function of the distance along the line of action, e.g.

$$\varepsilon_{je} = C_e (S_j - S_e)^2 \quad \text{and} \quad \varepsilon_{jd} = C_d (S_j - S_d)^2$$

(2.34)

where $S_j$ reflects the distance along the line of action from the pitch line; $S_d$ and $S_e$, the distance along line of action from pitch line to the start of disengagement cam and end of engagement cam; $C_d$ and $C_e$, disengagement and engagement cam relief, which are determined by:

$$C_e = \Delta_e / (S_{oe} - S_e)^2 \quad \text{and} \quad C_d = \Delta_d / (S_{od} - S_d)^2$$

(2.35)

Where $S_{od}$ and $S_{oe}$, represent distances along the line of action from pitch line to end of disengagement cam (tooth tip) and start of engagement cam; $\Delta_d$ and $\Delta_e$, maximum disengagement and engagement tooth relief for the tooth pair, which is the total or combined tooth pair relief at the start and end of an ideal mesh.

Figure 7 shows how this model in Figure 6 relates to the real gear tooth.

Suppose the tooth shown in Figure 7 is the driven gear. In Figure 7, the point P is the pitch point of the tooth pair; point E is the start point of engagement; point A is the end point of engagement; point C is the start point of disengagement; and point D is the end point of disengagement.
Tooth profile modification can be divided into two parts: one is the engagement part, which is the tooth face between points E and A; another is the disengagement part, which is the tooth face between points C and D. When two gears are in mesh, modifying the tooth tip of one gear is the same as modifying the tooth root of the other gear.
Hence the disengagement part can be defined as the driving gear tooth face between point A and E.

To simulate the wear of a tooth face, two parameters needed to be specified. One is $P_{SOD} / P_{SOE}$, which is the length of profile modification as a percent of the length of total disengagement or engagement measured along the line of action. This parameter determines the length of tooth wear. Another one is $\Delta_d$ and $\Delta_e$, which is the maximum disengagement and engagement tooth relief for the tooth pair, which is the total or combined tooth pair relief at the start and end of an ideal mesh. This parameter determines the maximum wear at the tip or the root of the gear tooth.

2.5. Discussions of Results

As outlined above, there are two parameters which control the simulated tooth wear. A parametric study was conducted to evaluate the change in gear-mesh stiffness under different wear conditions. The analysis given above, along with its corresponding computer code was used to analyze the gear-mesh stiffness change of a gear system under different wear conditions.

For simplicity, a single stage gear mesh was chosen (one input gear and one output gear). The pertinent parameters for the system are given in Table 1. An example of the input data for the system is given in Table 2.

</table>
First, let's analyze the wear of engagement:

1. $P_{\text{soe}}$ was fixed at 50%, that is, the length of wear was fixed; the tip relief, $\Delta_e$, was chosen as 1e-5 in, 2e-5 in, and 4e-5 in. The results are shown in Figure 8.

2. $\Delta_e$ was fixed at 2e-5 in, that is, the maximum amount of wear at the tip or the root of the gear tooth was fixed; the length of wear, $P_{\text{soe}}$, varied at 50%, 60%, 70%, and 80%. The results are shown in Figure 9.

Second, let's analyze the wear of disengagement part:

1. $P_{\text{soo}}$ was fixed at 50%, that is, the length of wear was fixed; the tip relief, $\Delta_d$, was chosen as 1e-5 in, 2e-5 in, and 4e-5 in. The results are shown in Figure 10.

2. $\Delta_d$ was fixed as 2e-5 in, that is the maximum amount of wear at the tip or the root of the gear tooth was fixed; the length of wear, $P_{\text{soo}}$, varied as 50%, 60%, 70%, and 80%. The results were shown in Figure 11.

Finally, both the wear of the engagement and disengagement were considered:

1. $P_{\text{soe}}$ and $P_{\text{soo}}$ were fixed at 50%, that is the length of wear was fixed; the tip relief, $\Delta_e$ and $\Delta_d$, were chosen as 2e-5 in, 4e-5 in, 6e-5 in, and 8e-5 in. The results are shown in Figure 12.

2. $\Delta_e$ and $\Delta_d$ were fixed at 2e-5 in, that is the maximum amount of wear at the tip or the root of the gear tooth was fixed; the length of wear, $P_{\text{soe}}$ and $P_{\text{soo}}$, varied as 50%, 60%, 70%, and 80%. The results are shown in Figure 13.
Figure 8. Mesh stiffness due to the tooth surface wear on engagement

(Different value of tip relief, while the wear length remains fixed)
Figure 9. Mesh stiffness due to tooth surface wear on engagement

(Different value of wear length, while the tip relief remains fixed)
Figure 10. Mesh stiffness due to tooth surface wear on disengagement

(Different value of tip relief, while the wear length remains fixed)
Figure 11. Mesh stiffness due to tooth surface wear on disengagement

(Different value of wear length, while the tip relief remains fixed)
Figure 12. Mesh stiffness due to tooth surface wear on both engagement and disengagement (Different value of tip relief, while the wear length remains fixed)
Figure 13. Mesh stiffness due to tooth surface wear on both engagement and disengagement (Different value of wear length, while tip relief remains fixed)
From Figure 8-13, it is obvious that the gear tooth damage due to surface pitting and wear can significantly change the phase of the mesh stiffness. The higher degree of surface pitting and wear, the more the phase of the mesh stiffness will shift.

2.6. Summary

A numerical model has been developed to simulate the gear mesh stiffness change resulting from gear tooth damage due to surface pitting and wear. The work in this chapter can be summarized as follows:

1. A method has been developed to simulate the tooth surface wear in a gear transmission system. The tooth surface wear level can be controlled by adjustment of both amplitude and length in the tooth profile modification.

2. The gear mesh model has been developed to provide the mesh stiffness with the effect of gear tooth damage due to various degrees of surface pitting and wear. It will be shown in the next chapter that these changes in gear mesh stiffness can be incorporated into a dynamic simulation of the gear transmission system for dynamic predictions.
3.1. Objectives

In the last two decades, problems arising from excessive gear tooth wear and gear tooth surface pitting in gear transmission systems have been of increasing concern for a variety of gear users. Although regular visual inspections and preventive maintenance can help to reduce the failure rate of gear systems, the cost and down time required make such programs inefficient and uneconomical.

Vibration signature analysis methodologies are being developed to non-intrusively examine the health and wear of gear transmission systems. Considerable success has been achieved in applying the Wigner-Ville distribution concept (WVD) [14-16] in machine health monitoring of gear transmission systems [17,18,24]. However, a complete vibration signature database is necessary for the development of an effective pattern recognition scheme. In order to populate such databases, the development of an accurate analytical procedure to predict vibrations in gear systems due to wear and fatigue failure is necessary.

The objective of this chapter is to develop a comprehensive procedure to simulate and analyze the vibration in a gear transmission system with effects of surface pitting and wear of the gear teeth under normal operating conditions. To simulate the vibration of the transmission system, the equations of motion were established individually for each rotor-gear-bearing system. The changes of the mesh stiffness at one particular tooth
location or a number of consecutive teeth due to the effects of surface pitting and wear were incorporated into the gear-rotor model for the dynamic simulation [11-13]. The dynamics of each gear-rotor system were coupled with each other through the gear mesh interacting forces. The coupling between the rotors and the casing structure were joined through the bearing support forces. The global vibrations of the system were evaluated by solving the transient dynamics of each rotor system simultaneously with the vibration of the casing. In order to minimize the computational effort, the number of degrees-of-freedom of the system were reduced by using a modal synthesis procedure [11,12]. The results were evaluated by Wigner-Ville Distribution (WVD) [13-15].

3.2. Dynamics of the Gear-Shaft Configuration and the Gearbox System

The dynamics of the ith individual gear-shaft system can be evaluated through the equations of motion for the vibrations of an individual rotor-bearing-gear system as shown in Figure 14, given in matrix form, as

\[
[M]\{\ddot{W}_i\} + [K_s]\{\dot{W}_i\} = \{F_{bi}(t)\} + \{F_{gi}(t)\} + \{F_{ui}(t)\}
\]

(3.1)

where \([M]\) and \([K_s]\) are respectively the mass and shaft stiffness matrices of the rotor, \(\{W_i\}\) is the general displacement vector of the ith rotor in the its local coordinate system, and, \(\{F_{bi}(t)\}\), \(\{F_{gi}(t)\}\), and \(\{F_{ui}(t)\}\) are the force vectors acting on the ith rotor system due to bearing forces, gear mesh interactions, and mass-imbalances respectively.
The equation of motion of the gearbox with \( p \) rotor systems can be expressed as

\[
[M_c][\ddot{\mathbf{w}}_c] + [K_c][\mathbf{w}_c] = \sum_{i=1}^{p} [T_{ci}][F_b(t)]
\]  

Figure 14. Schematic of a rotor-gear bearing system.

where \([T_{ci}]\) represents the coordinate transformation between the \( i \)th rotor and the gearbox.
The bearing forces $\{F_{bi}(t)\}$ for the ith rotor can be evaluated as

$$
\{F_{bi}(t)\} = [C_{bi}][\{W_i\} - [T_{ic}][\dot{W}_{ci}]] + [K_{bi}][\{W_i\} - [T_{ic}][\ddot{W}_{ci}]]
$$

(3.3)

where $[C_{bi}]$ and $[K_{bi}]$ are respectively the damping and stiffness of the bearing, $[T_{ic}]$ is the coordinate transformation matrix for the gearbox with respect to the ith rotor, and $W_{ci}$ are the casing displacements at the rotor locations.

The gear forces generated from the gear mesh interaction[40] can be written as

$$
\{F_{gi}(t)\} = \{F_{gi}(t)\} + \{F_{gi}(t)\}
$$

(3.4)

where $\{F_{gi}(t)\}$ is the vector containing the gear forces and moments resulting from the relative rotation between the two mating gears and $\{F_{gi}(t)\}$ is the vector containing gear forces and moments due to the translational motion between the two gears.

In order to calculate the transient and steady state dynamics of the system, the coupled rotor and casing equations of motion must be solved simultaneously. To minimize the computational effort, the modal transformation [11,12] procedure is applied to reduce the degrees of freedom of the global equations of motion. Using $m$ undamped mode shapes of the ith rotor system $[\phi_{i1}, \phi_{i2}, \phi_{i3}, \ldots, \phi_{im}]$ and $m_c$ undamped mode shapes of the gearbox $[\phi_{c1}, \phi_{c2}, \phi_{c3}, \ldots, \phi_{cmc}]$, the rotor displacement for the ith rotor can be written as

$$
\{W_i\} = \sum_{j=1}^{m} A_{ij} \{\phi_j\}
$$

(3.5)

and, similarly, the gearbox displacements as

$$
\{W_c\} = [\phi_c][A_c]
$$

(3.6)
where \( \{ A_i \} \) and \( \{ A_c \} \) are the modal time functions of the ith rotor and the gearbox respectively. Using the expansion in equation (3.5), the equations of motion for the ith rotor in equation (3.1) can be written as

\[
[M \begin{bmatrix} \phi_e \end{bmatrix} \dot{A}_i] + [K, \begin{bmatrix} \phi_e \phi_i \end{bmatrix}] \{ A_i \} = \{ F_i(t) \} + \{ F_{ui}(t) \} + \{ F_{wi}(t) \} \quad (3.7)
\]

Premultiplying by \( [\phi_i]^T \) and using the orthogonality conditions of the mode shapes [21], the ith rotor equations of motion can be written as

\[
\{ \dot{A}_i \} + \left[ \Lambda^2 \right] \{ A_i \} = \{ F_{bi} \} + \{ F_{gi} \} + \{ F_{ui} \} \quad (3.8)
\]

where \( \left[ \Lambda^2 \right] \) is the diagonal matrix of the squares of the natural frequencies of the system.

For the gearbox system, a similar transformation is carried out and equation (3.2) can be written as

\[
\{ \dot{A}_c \} + \left[ \Lambda^2 \right] \{ A_c \} = \{ F_{cb} \} \quad (3.9)
\]

For the system of \( k \) rotors, equation (3.8) can be repeated \( k \) times and solved with the casing equation (3.9) simultaneously for the modal accelerations \( \{ A_i \} \) and \( \{ A_c \} \). A numerical integration scheme is used to integrate the accelerations to obtain velocities and displacements at each time step for transient calculations [11].

3.3. Vibration Signature Analysis

3.3.1 Joint Time-Frequency Analysis

To examine the vibration signal, a joint time-frequency analysis method was chosen. This approach was chosen because of the large amount of information represented in the joint time-frequency results which can not be represented separately in either the time domain or the frequency domain. The joint time-frequency analysis will
provide an instantaneous frequency spectrum of the system at every instant of the revolution of the pinion while a Fourier Transform can only provide the average vibration spectrum of the signal obtained during one complete revolution. In other words, the time-changing spectral density from the joint time-frequency spectra will provide information concerning the frequency distribution concentrated at that instant around the excited instantaneous frequency which cannot be obtained in a regular vibration frequency spectrum. The following is a description of the joint time-frequency analysis method.

To examine the vibration signal in a joint time-frequency domain, the Wigner-Ville method [14,15] was used in this research. While the Fast Fourier Transform (FFT) technique can provide the spectral contents of the time signal, it cannot distinguish time phase change during a complete cycle of operation. In other words, it assumes that the time signals are repeatable for each time data acquisition window without considering the effects of any magnitude and phase changes during the sampling period. The Wigner-Ville distribution will provide an interactive relationship between time and frequency during the period of the time data window. The comprehensive representation of the vibration signal using the WVD method is the primary reason that it was used to compare the predicted and experimental vibration results. The WVD (Wigner-Ville Distribution), in a Discrete form, can be written as:

\[
W_x(nT, f) = 2T \sum_{i=-L}^{L} x(nT + iT)x^*(nT - iT) \cdot e^{-j4\pi ft}
\]  

(3.10)

where
$W(t, f) =$ the Wigner-Ville distribution in both the time domain $t$ and frequency domain $f$.

$x(t) =$ the time signal

$T =$ the sampling interval

$L =$ the length of time data used in the transform

To allow sampling at the Nyquist rate and eliminate the concentration of energy around the frequency origin due to the cross product between negative and positive frequency [14,15], the analytic signal was used in evaluating the WVD. The analytic signal $s(t)$ is defined as

$$s(t) = x(t) + jH[x(t)]$$

(3.11)

where $H[x(t)]$ is the Hilbert transform of $x(t)$. However, an alternative approach can be used to calculate the analytic signal using the frequency domain definition. The analytic signal $s(t)$ can be evaluated by calculating the FFT of the time signal $x(t)$, then setting the negative frequency spectrum to zero. The analytic signal can be obtained by evaluating the inverse FFT of the spectrum.

To simplify the computational effort, the WVD can be evaluated using a standard FFT algorithm. Adopting the convention that the sampling period is normalized to unity, it is necessary only to evaluate the WVD at time zero. Hence

$$W_x(0, f) = 2 \sum_{i=-L}^{L} k(i)e^{-j2\pi fi}$$

(3.12)

where $k(i) = s(i) s^*(i)$.

In order to avoid a repetition in the time domain WVD, a weighting function [28] was added to the time data before the evaluation process. Such a process may decrease
the resolution of the distribution, but it will eliminate the repetition of peaks in the time
domain and the interpretation of the result is substantially easier.

3.3.2 Frequency Domain Analysis

The frequency spectrum is found by applying a Discrete Fourier Transform (DFT)
on the time averaged signal $x(t)$, such that the spectral components are

$$X(k) = T \sum_{t=0}^{N-1} x(t) \exp\left(\frac{-i2\pi k}{N}\right)$$  \hspace{1cm} (3.13)

where

$x(t)$ = time domain signal

$X(k)$ = frequency domain signal

$T$ = sampling time interval

$N$ = number of data points

The frequency components were examined in the frequency domain.

3.4. Discussions of Results

In order to examine the sensitivity of the system vibrations on gear tooth
imperfections, the vibrations in gear systems due to various levels of gear wear were
analyzed. The basic parameters used in this analysis are the magnitude and geometry of
tooth profile deviation and the number of teeth involved.

The model of rotor-gear system used in this analysis is shown in Figure 15. The
number of teeth in the gear model is 28. And the vibration analysis of this system under
various levels of gear wear are given as follows.
First, surface pitting on a single tooth is used with the magnitude of the tip relief given in Table 3. The damaged tooth is the 12th tooth from the reference point on the gear.

<table>
<thead>
<tr>
<th>Table III Magnitude of the Maximum Tip Relief</th>

</tr>
<tr>
<td>2nd tooth</td>
</tr>
<tr>
<td>3rd tooth</td>
</tr>
</tbody>
</table>

Figure 16-18 show the WVD, the time signal (to the left of the WVD), and the frequency spectra (below the WVD) of the vibrations of the corresponding system. In Figure 16, a small cross pattern had developed in the WVD around the 154 degrees location which is the exact mesh time of the 12th tooth. A small phase shift is also detected in the time signal at that location. As the damage of the tooth becomes more severe (increase in the magnitude of the profile modification), the cross pattern is more obvious and the phase shift is getting more pronounced, as shown in Figure 17 and Figure 18.

Secondly, the dynamics involved with damage on two consecutive teeth (12th and 13th) was simulated. During this simulation the wear on the first tooth (12th) is kept constant while the amounts of wear on the second tooth (13th) increased similarly to that given in Table 3.
Figure 19 - 21 show the WVD, the time signal, and the frequency spectra of the vibrations of a corresponding system with damage on two consecutive teeth. When the damage on the tooth is increased, the cross pattern shown in the WVD is not as sharp as those with single tooth damaged. However the sideband components at the tooth pass frequency increase with increasing damage, as seen in the frequency spectra of Figures 19- 21. In addition, the once per revolution low frequency component increases along with its sidebands. As seen in the time domain, the phase shift becomes more pronounced also.

Thirdly, the dynamics involved in three consecutive teeth (12th, 13th and 14th) were examined. In this case, the wear/damage in the first and the second teeth are kept constant, the amounts of wear in the third tooth increase similarly to those given in Table 3.

Figure 22 - 24 show the WVD, the time signal, and frequency spectra of the vibrations of the corresponding system with three consecutive teeth damaged. The frequency components near the tooth pass frequency show very small changes from those with two consecutive teeth damaged, Figure 19 -21. However, the frequency components near the shaft frequency has acquired a substantial increase with large sidebands.

Based on the above discussion, one can generalize the effects of single and multiple consecutive tooth damage on the vibrations of a gear transmission system. Using the WVD technique, 3-D image pattern recognition, procedures can be developed to identify various combinations and levels of tooth damage.

3.5. Summary

A numerical procedure has been developed to simulate the vibration in a gear transmission system with effects of gear tooth damage due to wear and pitting. The work presented in this chapter can be summarized as follows:

1) A modal synthesis methodology has been used to simulate the dynamics of gear transmission systems. The computational efforts has been greatly reduced by modal transformation.

2) The gear mesh model developed to simulate the gear tooth damage due to wear and pitting can easily be incorporated into the global transmission system for dynamics predictions.

3) The Wigner-Ville distribution (WVD) method provides a comprehensive representation of the vibration signal. It was successfully used to verify the analytical model.

4) The WVD method provides detailed information. Hence, using the time averaging technique, frequency spectrum analysis, and the WVD, a signature analysis scheme can be developed to examine and characterize the vibration signal of the gear system.

5) A parametric study of the effects on the vibration signal due to various degrees of pitting and wear damage, could provide a comprehensive database for gear fault detection and damage estimation research.
4.1 Objective

The objective of this chapter is to examine and compare the three different approaches to detect gear wear and failure. The frequency domain analysis is based on the spectral display from a Fast Fourier Transform algorithm. The time domain analysis includes the time synchronous averaged signal, and the statistical based techniques FM0, FM4, NA4*, and NB4* applied to the time averaged signal. The joint time-frequency analysis uses the WVD on the vibration data with special windowing techniques. All of the analysis methods are applied to the vibration data of a failure from the spiral bevel gear fatigue test rig in the NASA Lewis Research Center. Results from the various methods are compared and general conclusions are drawn from the results.

4.2 Technical Approach

As discussed in the previous section, three major methodologies: A) the frequency domain approach, B) the time domain approach, and C) the joint time-frequency approach are used in this study. The following is a description of the three methodologies:

(A) Frequency Domain Techniques

The frequency spectrum is found by applying a discrete FFT on the time averaged signal $x(t)$, such that the spectral components are
\[ X(k) = T \sum_{i=0}^{N-1} x(t) \exp(-j2\pi ik/N) \]  \hspace{1cm} (4.1)

where \( x(t) \) = time domain signal, \( X(k) \) = frequency domain signal, \( T \) = sampling time interval, \( N \) = number of data points. The frequency components are examined in the frequency domain and compared with those obtained at various stages of the fault development in the spiral bevel pinion.

\textbf{(B) Time Domain Techniques}

Four different time domain techniques for early detection of gear tooth damage are used in this study for evaluation and comparison. All of the time domain techniques are applied to the vibration signal after it has been time synchronously averaged. These techniques are:

FM0, FM4, NA4*, and NB4*. These parameters are defined as follows:

FM0\textsuperscript{[46]} is a course fault detection parameter that compares the maximum peak to peak amplitude to the sum of the mesh frequencies and its harmonics

\[ FM0 = \frac{PP}{\sum_{i=1}^{n} A(f_i)} \]  \hspace{1cm} (4.2)

where \( PP \) = maximum peak to peak amplitude in signal, \( A(f) \) = amplitude at mesh frequency and harmonics, \( n \) = total number of harmonics in frequency range, and FM4\textsuperscript{[46]} is an isolated fault detection parameter, and is given by the normalized kurtosis, of the resulting difference signal as

\[ FM4 = N \sum_{i=1}^{N} (d_i - \bar{d})^4 / \left( \sum_{i=1}^{N} (d_i - \bar{d})^2 \right)^2 \]  \hspace{1cm} (4.3)
where \( d(t) = A(t) - R(t) \), \(-d^2\) = mean value of \( d(t)\), \( A(t)\) = original time synchronous signal, \( R(t)\) = regular meshing components plus their first order side bands, and \( N \) = total number of data points in the time signal.

\( NA4^*[45-48] \) is a general fault detection parameter with trending capabilities. A residual signal is constructed by removing regular meshing components from the time averaged signal. For \( NA4 \), the first order sidebands stay in the residual signal and the fourth statistical moment of the residual signal is then divided by the averaged variance of the residual signal, raised to the second power. The average variance is the mean value of the variance of all previous records in the run ensemble. This allows \( NA4 \) to compare the current gear vibration with the baseline of the system under nominal conditions. \( NA4 \) is given by the quasi-normalized kurtosis equation shown below:

\[
NA4^*(M) = N \sum_{i=1}^{N} (r_i - \bar{r})^4 / \left( \frac{1}{M} \sum_{j=1}^{N} \sum_{i=1}^{N} (r_{ij} - \bar{r}_j)^2 \right)^2
\]  

(4.4)

where \( r \) = residual signal, \( \bar{r} \) = mean value of residual signal, \( N \) = total number of data points, in one time record, \( i \) = data point number in time record, \( j \) = time record number, and \( M \) = current time record number in run ensemble.

An enhancement to this parameter is given by \( NA4^* \), in which the value of the averaged variance is "locked" when the instantaneous variance exceeds a pre-determined value.[47] This provides \( NA4 \) with enhanced trending capabilities, in which the kurtosis of the current signal is compared to the variance of the locked baseline signal under nominal conditions.
NB4 is another parameter similar to NA4 that also uses the quasi-normalized kurtosis given in equation (4.4). The major difference is that instead of using a residual signal, NB4 uses the envelope of the signal bandpassed about the mesh frequency. Again, as with NA4*, NB4* is an enhancement to the NB4 parameter, in which the value of the average variance is "locked" when the instantaneous variance exceeds a pre-determined value. The equation for NB4* is given below:

\[\text{NB4}^*(M) = N \sum_{i=1}^{N} (s_i - \bar{s})^4 / \left( \frac{1}{M} \sum_{j=1}^{M} \left[ \sum_{i=1}^{N} (s_{ij} - \bar{s}_j)^2 \right] \right)^2 \] (4.5)

and

\[s(t) = \text{magnitude of } \{b(t) + i \{H[b(t)]\}\} \] (4.6)

where \(b(t)\) = time averaged signal bandpassed filtered about the meshing frequency, \(H[b(t)]\) = the Hilbert Transform of \(b(t)\), \(N\) = total number of data points in one time record, \(i\) = data point number in time record, \(j\) = time record number, and \(M\) = current time record number in run ensemble.

\(\text{(C) Joint Time-Frequency Technique}\)

To examine the vibration signal in a joint time-frequency domain, the Wigner-Ville method[14-18,41,49] is used in this study. While the FFT technique (eq. 4.1) can provide the spectral contents of the time signal, it cannot distinguish time phase change during a complete cycle of operation. In other words, it assumes that the time signals are repeatable for each time data acquisition window without considering the effects of any magnitude and phase changes during the sampling period. The Wigner-Ville distribution will provide an
interactive relationship between time and frequency during the period of the time data window. The WVD (Wigner-Ville Distribution) can be written as:

$$W(t, f) = \sum_{-\infty}^{\infty} x(t + \frac{\tau}{2}) x^*(t - \frac{\tau}{2}) e^{-j2\pi fr} d\tau$$

(4.7)

To allow sampling at the Nyquist rate and eliminate the concentration of energy around the frequency origin due to the cross product between negative and positive frequency,[14,15] the analytic signal was used in evaluating the WVD. The analytic signal $s(t)$ is defined as

$$s(t) = x(t) + jH[x(t)]$$

(4.8)

where

$$H[x(t)] = \text{the Hilbert transform of } x(t) \text{ defined by:}$$

$$H[x(t)] = \frac{1}{\pi} \int_{-\infty}^{\infty} \frac{x(\xi)}{t-\xi} d\xi$$

(4.9)

However, an alternative approach can be used to calculate the analytic signal using the frequency domain definition. The analytic signal $s(t)$ can be evaluated by calculating the FFT of the time signal $x(t)$, then setting the negative frequency spectrum to zero. The analytic signal can be obtained by evaluating the inverse FFT of the spectrum. To simplify the computational effort, the WVD can be evaluated using a standard FFT algorithm.

Adopting the convention that the sampling period is normalized to unity, equation (4.7) can be rewritten as

$$W_x(n, f) = 2 \sum_{i=-L}^{L} x(n+i) x^*(n-i) \cdot e^{-j4\pi fn}$$

(4.10)

As for the continuous time case, it is necessary only to evaluate the WVD at time zero.
Hence

\[ W_x(0, f) = 2 \sum_{i=-L}^{L} k(i) e^{-j4\pi f_i} \]  

(4.11)

where \( k(i) = s(i) s^*(-i) \). Equation (4.12) can be evaluated using the discrete FFT algorithm.

In order to avoid a repetition in the time domain WVD, a weighting function[18] is added to the time data before the evaluation process. Such a process may decrease the resolution of the distribution, but it will eliminate the repetition of peaks in the time domain and the interpretation of the result will be substantially easier.

4.3 Description of Experimental Procedure

The fatigue damage on the test pinion shown in Figures 25 to 32 was obtained using the spiral bevel gear fatigue test rig illustrated in figure 33, at the NASA Lewis Research Center. The primary purpose of this rig is to study the effects of gear tooth design, gear materials, and lubrication types on the fatigue strength of aircraft quality gears.[50] Because spiral bevel gears are used extensively in helicopter transmissions to transfer power between nonparallel intersecting shafts, the use of this fatigue rig for diagnostic studies is extremely practical. Vibration data from an accelerometer mounted on the pinion shaft bearing housing was captured using a personal computer with an analog to digital conversion board and anti-aliasing filter. The 12-tooth test pinion, and the 36-tooth gear have; 0.5141 in pitch, 35 degree spiral angle, 1 in. face width, 90 degree shaft angle, and 22.5 degree pressure angle. The pinion transmits 720 hp at nominal speed of 14,400 rpm. The test rig was started and stopped several times for gear damage inspection. The test was ended at
17.79 operational hours when a broken portion of a tooth was found visually during one of the shutdowns.

4.4. Discussions of Results

A series of pictures showing the deterioration of the pinion teeth at various stages of the test are illustrated in figures 25 to 32. In figure 1 the initiation of a small pit on one of the pinion teeth during the first shutdown, at about five and a half hour into the test is shown. As the test progressed, the rig was shut down seven more times to examine the severity of the pitting and its relationship with the corresponding vibrations. Figures 26 to 28 show the increase of the damaged area at the pinion tooth as the elapsed time increased to 6.55, 8.55, and 10.03 hr respectively. Note that in figure 29, as the elapsed time increased to 12 hr, the damage of the pinion tooth increased to 75 percent of the tooth surface. At this stage, pitting also initiated on the adjacent tooth and continued to grow as the time increased to 14.53 hr, figure 30. At 16.16 hr, the damage has grown to three adjacent teeth as shown in figure 31. The test was terminated when a breakage is detected on one of the three heavily pitted teeth at 17.79 hr, as shown in figure 32.

Figure 34 depicts the running speed of the test rig during various stages of the experiment. Note that there is some fluctuations present in the running speed after each shutdown, with a magnitude of approximately 6 percent about the nominal pinion speed of 14,400 rpm. There is a sharp change in speed at approximately 8.75 hr. These variations in speed create a substantial effect on the vibration signal, which is amplified in the NA4 (fig. 37), NB4 (fig. 38), and the WVD (fig. 45) analysis.
Figure 25. Photograph of pinion damage at 5.50 hr.

Figure 26. Photograph of pinion damage at 6.55 hr.

Figure 27. Photograph of pinion damage at 8.55 hr.

Figure 28. Photograph of pinion damage at 10.03 hr.

Figure 29. Photograph of pinion damage at 12.03 hr.

Figure 31. Photograph of pinion damage at 16.16 hr.

Figure 32. Photograph of pinion damage at 17.79 hr.

Figure 33. Spiral bevel gear rig at NASA Lewis Research Center.
Figure 35 shows the results of the FM0 analysis. As seen from the figure, FM0 shows only moderate changes as the damage starts and progresses. It does not provide any indication as the damages extends to the adjacent teeth, resulting in pinion tooth fracture. The majority of the variations in the FM0 parameter are most probably due to the speed changes experienced during the test.

Results from the FM4 parameter, as seen in figure 36, shows a possible reaction as the pitting started to occur, however, it does not provide any coherent indication of the severity of the pitting as the damage increased. In addition, it does not provide any information to distinguish the pitting of a single or multiple teeth.

Results from NA4 and NA4* are illustrated in figure 37. It is obvious from the figure that both NA4 and NA4* provide a very good indication of the pitting development on the pinion tooth. The magnitude of the parameter increases to a nondimensional value of 7 after shutdown #2 at 6.55 hr, and further to a value of 17 when the pitting covers 75 percent of the tooth surface at 8.5 hr. As expected, the "locked" denominator in NA4* provides a more robust indication as the pitting progresses.[45,47] Again, both parameters are very sensitive to the speed variations, especially after shutdown #3 and #6.

The NB4 and NB4* parameters, as shown in figure 38, show a very similar trend to those of NA4 and NA4*, with a more robust indication to the severity of the damage. However, both NA4 and NB4 did not provide any type of indication as the damage spread to other teeth, and finally as tooth fracture occurred.
Figure 34. Rig operating speed at various run times.

Figure 35. FM0 parameter at various run times.

Figure 36. FM4 parameter at various run times.
Figure 37. NA4 and NA4* at various run times.

Figure 38. NB4 and NB4* at various run times.
Figure 39 shows a WVD (and corresponding intensity scale) and below the WVD the frequency spectrum (from FFT analysis) of a uniform sine wave signal shown at the left side of the figure. Note that only the frequency component of the input frequency is detected by both the frequency domain analysis and the joint time-frequency distribution. The WVD does not exhibit any changes during the 1 cycle (0 to 360 degrees) rotation of the shaft.

When a short term amplitude and phase change is added to the system, as shown in figure 40, the frequency spectrum remains virtually unchanged. The WVD shows a dramatic change of the energy distribution pattern at the location where the change occurs. The lighter shades of the distribution display indicates a smaller vibration amplitude, which is shown by the time signal at the left side of the figure. Such an effect could be possibly caused by a chipped or cracked tooth. Figure 41 shows the effects of a short term amplitude increase in the time signal to simulate vibrations caused by gear tooth surface damage. Note that the frequency spectrum remains the same showing only the component of the exciting frequency while the WVD again provides a good indication of the amplitude increase by the widening of the shaded area to a diamond shape at the corresponding "damaged" tooth location. Figure 42 shows the effects of a time decaying short term amplitude and phase change signal. The WVD shows a half diamond shape of shaded area, similar to that of figure 40, at the location where the amplitude and phase changes are presented. As seen in figure 42, the frequency spectrum gives very little indication of the signal change.

Figure 47. Application of WVD to spiral bevel gear vibration signal at 12.09 hr

Figure 48. Application of WVD to spiral bevel gear vibration signal at 14.59 hr

Figure 49. Application of WVD to spiral bevel gear vibration signal at 16.22 hr

Figure 50. Application of WVD to spiral bevel gear vibration signal at 17.72 hr
Figures 43 to 50 show the WVD and frequency spectra of the spiral bevel pinion vibration at various stages of damage, corresponding to the photographs given in figures 25 to 32. Figure 43 shows the occurrence of the initial pitting at around 200 degrees from the triggering point of the gear, at 5.5 hr, of running time. At 6.55 hr, the pitting on the tooth surface progressed to a more noticeable stage, as shown in figure 26, the WVD pattern, figure 44, begins to adopt those of a short term amplitude and phase change as illustrated in figure 42. At this stage, a Cross pattern appeared in the joint time frequency domain (WVD) as the damaged gear tooth produced a change in the frequency components other than the mesh frequency. Due to the speed increase at 8.55 hr, the overall WVD amplitude increases substantially as shown in figure 45. At the running time of 10.03 hr, the corresponding WVD in figure 46 shows the initiation of a cross pattern as surface pitting in the damaged tooth becomes more pronounced which can also be evidenced from the photograph of the pinion gear in figure 28. This phenomenon is also evident in the frequency spectrum with the existence of sideband components. At 12.03 hr, when the pitting on the pinion tooth has extended to about 75 percent of the tooth surface as shown in figure 29, the WVD pattern exhibits a solid cross pattern extending over the mesh frequency and several of its adjacent sidebands. The high concentration in the WVD energy and the initiation of a second cross pattern at 14.53 hr, figure 48, shows the advancement of the pitting process on second tooth, as illustrated in figure 30. This is further confirmed by the large amplitude of sideband component (above mesh) in the frequency spectrum. At 16.16 hr, as seen in figure 49, the WVD pattern changes, showing more advanced damage pattern similar to the multiples of the decay of a single short term amplitude increase and phase change demonstrated in figure 42. Such phenomenon is due to the pitting of three
consecutive teeth in the pinion gear as shown in the picture given in figure 31. The frequency spectrum in figure 49 shows a substantial amplitudes increase in the sideband components. The discontinuity of the WVD at the mesh frequency, shown in figure 50, similar to the example shown in figure 16 due to the short term phase change, is probably the result of the instantaneous phase change caused by the fractured tooth, as illustrated in figure 32. The two cross patterns in the WVD is very distinct as the effects of pitting at the teeth adjacent to the fracture tooth become more pronounced. Note, also that, as given in figure 50, the amplitude of the sideband frequencies(above and below the mesh frequency) increase substantially.

4.5 Conclusions

Based on the results of the application of the various aforementioned methods, the following conclusions can be made:

1) The FM0 parameter shows only moderate changes as the damage starts and progresses. It also fails to indicate the fracture of the pinion tooth.

2) The FM4 parameter shows a possible reaction to the start of the pitting process, however, no coherent indication is provided for the growth and severity of the pit.

3) The NA4* and NB4* parameters show good reactions to the initial pitting damage and very nice indications for the growth and severity of the pitting damage. However their indications for the tooth fracture is somewhat unclear.

4) The WVD provides vital information concerning both the severity and the location of the pitting process in the gear system.
5) The fracture of the gear tooth and its exact location can be pinpointed using the WVD technique. However, a machine vibration signature database is required to interpret the resulting WVD.

6) The occurrence and the severity of gear tooth failure can be reliably detected using a combination of the time averaging, the frequency analysis, and the WVD techniques.
CHAPTER 5
ANALYSIS OF THE EFFECTS OF SURFACE PITTING AND WEAR ON THE VIBRATIONS OF A GEAR TRANSMISSION SYSTEM

5.1 Objective

Vibration signature analysis methodologies are being developed to non-intrusively examine the health and wear of gear transmission systems. Using spectral analysis, the amplitude of the frequency spectrum of the measured vibration signal is calculated and displayed in a continuous manner. However, the spectral analysis technique is difficult to apply in a highly complex system where the large number of spectral lines often makes it difficult to detect significant changes in the spectrum. Another methodology is the joint time-frequency approach which applies the Wigner-Ville distribution (WVD) [14-16] on the time vibration signal of the system. Unlike the regular Fourier transform process, the WVD provides an instantaneous frequency spectrum of the system at any instant throughout the sampling period (while FFT provides a averaged frequency spectrum of the total sampling period). The spectral density of the fundamental exciting frequency and its sidebands change as the shaft rotates through a complete revolution. Some success has been achieved in applying the WVD concept in the health monitoring of gear transmission systems[16-18,26]. However, a complete vibration signature database is needed for development of an effective pattern recognition scheme. In order to populate such databases, the development of an accurate analytical procedure to predict vibrations in gear systems due to wear and fatigue failure is necessary.

The objective of this paper is to develop a comprehensive procedure to simulate and analyze the vibration in a gear transmission system with effects of surface pitting and wear of the
gear teeth under normal operating conditions. The effects of changes in magnitude and phase of the mesh stiffness at one particular tooth or a number of consecutive teeth were evaluated in order to simulate the effects of surface pitting and wear. The effects of these localized changes in the gear mesh were incorporated into each gear-rotor model for the dynamic simulation[11,51,52]. The dynamics of each gear-rotor system were coupled with each other through the gear mesh interacting forces. The coupling between the rotors and the casing structure were generated through the bearing support forces. The global vibrations of the system were evaluated by solving the transient dynamics of each rotor system simultaneously with the vibration of the casing. In order to minimize the computational effort, the number of degrees-of-freedom of the system were reduced by using a modal synthesis procedure[11,51]. The global transient dynamics of the overall transmission system were calculated in the modal coordinates where the modal accelerations were integrated numerically to obtain the velocities and displacements at each time step. An FFT procedure was used to transform the transient vibrations into the frequency domain for signature analysis. In addition, the Wigner-Ville distribution[14-18,26,53] was also used to examine the gear vibrations in the joint time-frequency domain for vibration pattern recognition. Experimental vibration results obtained from a gear fatigue test rig at NASA Lewis Research Center[48] were used to verify the analytical procedure.

5.2. Solution Procedures

5.2.1 Dynamics of the Gear-Shaft Configuration and the Gearbox System
The dynamics of the \ith\ individual gear-shaft system can be evaluated through the equations of motion for the vibrations of a individual rotor-bearing-gear system as shown in Figure 51[11,51], given in matrix form, as

\begin{equation}
[M] \{\ddot{W}_i\} + [K_i] \{W_i\} = \{F_{bi}(t)\} + \{F_{gi}(t)\} + \{F_{ui}(t)\}
\end{equation}

(5.1)

where \([M]\) and \([K_i]\) are respectively the mass and shaft stiffness matrices of the rotor, \(\{W_i\}\) is the general displacement vector of the \ith\ rotor in its local coordinate system, and, \(\{F_{bi}(t)\}\), \(\{F_{gi}(t)\}\), and \(\{F_{ui}(t)\}\) are respectively the force vectors acting on the \ith\ rotor system due to bearing forces, gear mesh interactions, and mass-imbbalances. In this model, the dynamics between the gearbox and the rotor are coupled through the bearing forces, which are evaluated by the relative motion between the rotor and the gearbox. The interactions between the each individual rotor are coupled through the gear forces generated by the relative motion of the two mating gears at the mesh point.

The equations of motion of the gearbox with \(p\) rotor systems can be expressed as

\begin{equation}
[M_c] \{\ddot{W}_c\} + [K_c] \{W_c\} = \sum_{i=1}^{p} [T_{ci}] \{F_{bi}(t)\}
\end{equation}

(5.2)

where \([T_{ci}]\) represents the coordinate transformation between the \ith\ rotor and the gearbox.

### 5.2.2 Evaluation of Bearing Forces

The bearing forces \(\{F_{bi}(t)\}\) for the \ith\ rotor can be evaluated as
\[ \{ F_{bi}(t) \} = [C_{bi}] (\{ \dot{W}_i \} - [T_{ic}] \{ \dot{W}_{ci} \}) + [K_{bi}] (\{ W_i \} - [T_{ic}] \{ W_{ci} \}) \]  

(5.3)

where \([C_{bi}]\) and \([K_{bi}]\) are respectively the damping and stiffness of the bearing, \([T_{ic}]\) is the coordinate transformation matrix for the gearbox with respect to the ith rotor, and \(W_{ci}\) are the casing displacements at the rotor locations.

5.2.3 Evaluation of Gear Forces

The gear forces generated from the gear mesh interaction\[54\] can be written as

\[ \{ F_{g}(t) \} = \{ F_{n}(t) \} + \{ F_{u}(t) \} \]  

(5.4)

where \(\{ F_{n}(t) \}\) is the vector containing the gear forces and moments resulting from the relative rotation between the two mating gears and \(\{ F_{u}(t) \}\) is the vector containing gear forces and moments due to the translational motion between the two gears. The forces and the torsional moments due to relative rotation between the kth location of the ith rotor and the lth location of the jth rotor, can be respectively expressed\[54, 10\] as

\[ \{ F_{nk}(t) \} = [D_{g}] [K_{gij}] ([R_{ik} \theta_{ik}] - [\bar{R}_{jl} \bar{\theta}_{jl}]) \]  

(5.5)

\[ \{ M_{nk}(t) \} = R_{i} [D_{g}] [K_{gij}] ([R_{ik} \theta_{ik}] - [\bar{R}_{jl} \bar{\theta}_{jl}]) \]  

(5.6)

where \(R_{ik}\) and \(\theta_{ik}\) are the radius and angular displacements in the ith-rotor gear localized gear rotational coordinates, \(\bar{R}_{jl}\) and \(\bar{\theta}_{jl}\) are radius and angular displacements of the lth location at the jth rotor in the ith-rotor localized gear rotational coordinates, \([K_{gij}]\) is the gear mesh stiffness matrix between the ith and jth rotors, and \([D_{g}]\) is a diagonalized matrix transforming the
localized gear coordinates into the ith rotor coordinate system. In addition, the translational forces can be represented by

\[
\{F_{ik}(t)\} = [D_{ij} \{K_{ij}\}]^T \{D_{ji}J^I\} ([T_{ij}] \{W_{ji}\} - \{W_{ik}\})
\]  

(5.7)

where \([T_{ij}]\) is the transformation matrix between the ith and jth rotor coordinates. For a rotor with one gear mesh, the gear force vector \(\{F_{g}(t)\}\) defined by equation (5.4) will have non-zero elements only at the gear location, i.e., the kth station. As the gear rotates, the stiffness of the gear mesh changes as the gear mesh progresses from single to multiple tooth contact. This cycling effect of the gear mesh stiffness is the main source for the mesh frequency excitation in the system.

5.2.4 Modal Synthesis Procedure

In order to calculate the transient and steady state dynamics of the system, the coupled rotor and casing equations of motion must be solved simultaneously. To minimize the computational effort, the modal transformation[11,51] procedure will be applied to reduce the degrees of freedom of the global equations of motion. Using \(m\) undamped mode shapes of the ith rotor system \(\{\phi_i, \phi_2, \phi_3, \ldots, \phi_m\}\) and \(m_c\) undamped mode shapes of the gearbox \(\{\phi_{c1}, \phi_{c2}, \phi_{c3}, \ldots, \phi_{cm}\}\), the rotor displacement for the ith rotor can be written as
\[ \{W_i\} = \sum_{j=1}^{m} A_j \{\phi_j\} \]

(5.8)

or

\[ \{W_i\} = [\phi_i] \{A_i\} \]

(5.9)

and, similarly, the gearbox displacements as

\[ \{W_c\} = [\phi_c] \{A_c\} \]

(5.10)

where \(\{A_i\}\) and \(\{A_c\}\) are the modal time functions of the ith rotor and the gearbox respectively.

Using the expansion in equation (8), the equations of motion for the ith rotor in equation (5.1) can be written as

\[
[M] [\ddot{\phi}_i] + [K_i] [\phi_i] = \{F_{bi}(t)\} + \{F_{gi}(t)\} + \{F_{ui}(t)\}
\]

(5.11)

Premultiplying by \([\phi_i]^T\) and using the orthogonality conditions of the mode shapes[11], the ith rotor equations of motion can be written as

\[
[\ddot{\phi}_i] + [\lambda^2] \{A_i\} = \{\overline{F_{bi}}\} + \{\overline{F_{gi}}\} + \{\overline{F_{ui}}\}
\]

(5.12)

where \([\lambda^2]\) is the diagonal matrix of the squares of the natural frequencies of the system, and

\[
\{\overline{F_{bi}}\} = [\phi_i]^T \{F_{bi}(t)\}
\]

(5.13)
\[
\{ \vec{F}_g \} = [\phi_i]^T \{ F_g(t) \} 
\]

(5.14)

\[
\{ \vec{F}_w \} = [\phi_i]^T \{ F_w(t) \} 
\]

(5.15)

For the gearbox system, a similar transformation is carried out as equation (2) can be written as

\[
\{ \vec{A}_c \} + [\Delta_c] \{ A_c \} = \{ \vec{F}_{cb} \} 
\]

(5.16)

For a system of k rotors, equation (5.12) can be repeated k times and solved with the casing equation (5.16) simultaneously for the modal accelerations \{A_i\} and \{A_c\}. A numerical integration scheme is used to integrate the accelerations to obtain velocities and displacements at each time step for transient calculations [11].

5.3. Signature Analysis of Vibration Signal

5.3.1 Frequency Domain Analysis

The frequency spectrum analysis is used by applying a discrete Fourier Transform on the average time signal \(x(t)\) such that the spectral components are

\[
X(k) = T \sum_{t=0}^{N-1} x(t) \exp\left(\frac{-j2\pi tk}{N}\right) 
\]

(5.17)
where \( x(t) \) is the time averaged of the vibration signal \( W(t) \) and \( T \) is the sampling interval. The frequency components are examined in the frequency domain and compared with those obtained at various stages of the fault development in the experimental gear test rig.

### 3.2 Joint Time-Frequency Analysis: The Wigner-Ville Distribution

To examine the vibration signal in a joint time-frequency domain, the Wigner-Ville method[14-16] is used in this study. The Wigner-Ville distribution will provide an inter-domain relationship between time and frequency during the period of the time data window. The WVD (Wigner-Ville Distribution) can be written as:

\[
WV(t,f) = \int_{-\infty}^{\infty} x(t + \frac{\tau}{2}) x^*(t - \frac{\tau}{2}) e^{i2\pi f \tau} d\tau
\]  

(5.18)

or in a discrete form as

\[
WV_x(nT,f) = 2T \sum_{i=-L}^{L} x(nT + iT) x^*(nT - iT). e^{i4\pi f T}
\]

(5.19)

where \( WV(t,f) \) is the Wigner-Ville distribution in both the time domain \( t \) and the frequency domain \( f \). To allow sampling at the Nyquist rate and eliminate the concentration of energy around the frequency origin due to the cross product between negative and positive frequency[14-16], the analytic signal was used in evaluating the WVD. The analytic signal \( s(t) \) is defined as

\[
s(t) = x(t) + jH[x(t)]
\]

(5.20)

Where \( H[x(t)] \) is the Hilbert transform of \( x(t) \) defined by:
\[ H[x(t)] = \frac{1}{\pi} \int_{-\infty}^{\infty} \frac{x(\xi)}{t - \xi} \, d\xi \]  \hfill (5.21)

However, an alternative approach can be used to calculate the analytic signal by the frequency domain definition. The analytic signal \( s(t) \) can be evaluated by calculating the FFT of the time signal \( x(t) \), then setting the negative frequency spectrum to zero. The analytic signal can then be obtained by evaluating the inverse FFT of the spectrum. To simplify the computational effort, the WVD can be evaluated using a standard FFT algorithm. Adopting the convention that the sampling period is normalized to unity, Equation (5.19) can be rewritten as

\[ WV_x (n, f) = 2 \sum_{i=-L}^{L} x(n + i) \, x^*(n-i) \, e^{ij\pi f} \]  \hfill (5.22)

As for the continuous time case, it is necessary only to evaluate the WVD at time zero. Hence

\[ WV_x (0, f) = 2 \sum_{i=-L}^{L} k(i) \, e^{ij\pi f} \]  \hfill (5.23)

where \( k(i) = s(i) \, s^*(-i) \). Equation (23) can be evaluated using the discrete FFT algorithm.

In order to avoid a repetition in the time domain WVD, a weighting function[26] is added to the time data before the evaluation process. Such process may decrease the resolution of the distribution, but it will eliminate the repetition of peaks in the time domain, and, thus the interpretation of the result will be substantially easier.

5.4. Description of Experimental Study

The experiment was performed on the spiral bevel gear fatigue test rig [48], as illustrated in Figure 52, at the NASA Lewis Research Center. The primary purpose of this rig is to study the effects of gear tooth design, gear materials, and lubricants on the fatigue strength of aircraft.
quality gears. Because spiral bevel gears are used extensively in helicopter transmissions to transfer power between nonparallel intersecting shafts, the use of this fatigue rig for diagnostic studies is practical. Vibration data from an accelerometer mounted on the pinion shaft bearing housing was captured by an analog to digital conversion board. The 12-tooth test pinion, and the 36-tooth gear have a 35 degree spiral angle, a 1 in. face width, a 90 degree shaft angle, and 22.5 degree pressure angle. The pinion transmits 720 hp at a nominal speed of 14,400 rpm. The test rig was stopped several times during the test for gear damage inspection. The test was concluded at 17.8 operational hours when a broken tooth was detected visually during one of the shutdowns.

Pictures of tooth damage on the pinion at various stages in the test are shown in Figure 53. At the first rig shut-down, at about 5.5 hours into the test, a small pit was observed on one of the teeth on the test pinion, as illustrated in Figure 53A. The test was stopped again at approximately 12 hours and the pitted area spread to cover approximately 75% of the face of the pinion tooth, as seen in Figure 53B. In addition, pitting started to appear on the adjacent teeth. Figure 53B shows the pinion at the end of the test, at 17.8 hours. It was found that one of the three heavily pitted pinion teeth had experienced a tooth breakage, losing one third of the tooth, as shown in the figure.

5.5. Discussions of Results

To study the effects of gear tooth pitting and wear on the dynamics of the rotor system, the numerical simulation procedure described above was used to model the vibrations of the pinion gear in the test rig. During the experimental study, vertical direction vibration signals

from the pinion gear are time synchronously averaged for spectral analysis and analysis using the joint time-frequency distribution (WVD). In order to perform an accurate comparison, the averaged time signal from the vertical vibration of the pinion gear is also generated using the numerical model. During these simulations, approximate gear mesh stiffness models are developed to simulate the effects of wear and pitting of the pinion tooth on the dynamics of the system.

As it has been established, the changes due to gear tooth wear or failure can be represented by the amplitude and phase changes in vibration, which, in turn, can be represented by magnitude and phase changes in mesh stiffness[17,18]. To demonstrate the effects of mesh stiffness change on gear vibration, the variation of the mesh stiffness model used for this study is given in Fig 54. The "undamaged" configuration of the mesh stiffness is given by 0 degree phase change (Fig. 54A), and 0% amplitude reduction (Fig. 54B). During the wear and pitting process, two types of stiffness changes are examined, i.e., the phase changes, shown in Figure 54A, and the amplitude changes, shown in Figure 54B. Figures 55 and 56 show the time, frequency, and joint time-frequency analysis (WVD) of the pinion gear vibration signals with the approximated changes in gear mesh stiffness.

Figure 55 shows the effects of mesh stiffness phase changes in the WVD representation of the predicted vibration signal. As seen in Figure 55, a phase change in the mesh stiffness at the 6th tooth of the 12-teeth pinion resulted in a temporary increase of amplitude and phase of the pinion vibration time signal during the 6th tooth pass location. As the phase shift in the mesh stiffness increases, from 1.5 degrees to 4.5 degrees, the changes in amplitude and phase in the vibration signal become more pronounced. In the frequency spectra, this change in mesh stiffness
will result in the increase of the amplitude in the sideband frequencies. However, as discussed earlier, although the frequency spectrum provides good indications of the existence of the non-synchronous components, it cannot distinguish the time locations of their occurrences. The joint time-frequency analysis using WVD, as indicated by the scale of shades given in Figure 55, shows the existence of various frequency components as the pinion rotates through a complete revolution of 360 degrees. Note that, in this case, the WVD shows a continuous excitation of the mesh frequency (12 x rotational speed) throughout the complete 360-degree revolution while subsynchronous components of 8 times, 4 times, and 1 times rotational speed are occurring at the 6th and 7th tooth pass locations.

Figure 56 shows the effects of reduction in mesh stiffness at the 6th gear location. With the reduction of mesh stiffness, a substantial change in the vibration at the 6th tooth pass location (150 - 180 degrees) is observed. Note that in the case of 50% stiffness reduction, the time vibration amplitude at the 6th tooth pass location (at approximately the 180 degree location for the 12 teeth pinion) almost vanishes and a much larger amplitude at the 7th tooth pass location is generated. In addition, the vibration amplitudes of the 8th and 9th tooth pass locations are reduced. These reductions in vibration amplitudes at mesh frequency resulted in a much higher sub-synchronous components in the frequency spectrum as shown in Figure 56C. The WVD shows a distinct type of cross pattern at the intersection of the mesh frequency and the 6th tooth pass location with a continuous mesh frequency component throughout the complete pinion revolution.

Figure 57 shows the pinion gear vibration signature analysis of the experimental time signal acquired at A) 12 hours when one tooth is severely pitted (Figure 53B), and B) 17.8
Figure 57 - Experimental pinion vibration due to damage on pinion teeth due to wear and pitting (a) single tooth (12hr), (b) three teeth (17.8hr)

Figure 58 - Gear mesh stiffness model to simulate damages in pinion gear teeth

Figure 59 - Numerically simulated pinion vibration due to damage on pinion teeth due to wear and pitting (a) Single tooth, (b) Three teeth.
hours, when three consecutive teeth are pitted and one has a tooth fracture (Figure 53C). To numerically simulate these phenomena, two gear mesh stiffness models, as shown in Figure 58A and 58B, which include a combination of phase shift and amplitude change, are introduced. Figure 58A represents the gear mesh stiffness for a heavily pitted tooth during a single tooth pass. The mesh stiffness is simulated by a 50% loss in stiffness at approximately first 20% of contacting period. Figure 58B represent the mesh stiffness, for three tooth pass period, consisting of one broken tooth with two heavily pitted teeth at the adjacent sides. Note that the stiffness of the middle (broken) tooth is simulated by a 50% loss of stiffness at the first 40% of its contacting period while the other adjacent(pitted) teeth are simulated by the stiffness reduction similar to that of the single tooth case as shown in Fig. 58A. Additional frictional effects are also added into the model to simulate the roughness of the tooth surface due to pitting. The simulated vibration signature of the pinion gear is given in Figure 59. Comparing Figures 59A and 57a, for the single tooth damage case at 12 hours, one may notice the similarities between both the frequency spectra and the WVD display. Some of the uneveness in the experimental time signal is mainly due to the modulation of frequencies due to other excitations in the test rig which are not numerically modeled. For the tooth break-off case at 17.8 hours, Figures 57B and 59B, both the numerical and the experimental WVD display a large cross pattern at the 6th tooth pass location due to tooth break-off. However, some discrepancies have been detected between the experimental and the numerical time signal at the 4th and 5th tooth pass locations. The experimental time signal consists of some higher frequency, smaller amplitude vibration modulation, which are not being numerically simulated. This additional modulated signal resulted in the excitation of the 14 times rotational speed component, as shown in the frequency
spectrum in Figure 57B, and, also, in turn, is responsible for the small differences created in the WVD.

5.6. Summary and Conclusions

A numerical procedure has been developed to simulate the dynamics of gear transmission systems with the effects of gear tooth damage due to wear and pitting. The work presented in this paper can be summarized as follows:

1) A modal synthesis methodology has been developed to simulate the dynamics of gear transmission systems. While the computational efforts has been greatly reduced by modal transformation, the numerical results generated maintains good accuracy.

2) Gear tooth damage due to wear and pitting can be simulated by amplitude and phase changes in the gear mesh stiffness model. The gear mesh model developed can easily be incorporated into the global transmission system for dynamic predictions.

3) Using the time averaging technique, frequency spectrum analysis, and the Wigner-Ville distribution, a signature analysis scheme can be developed to examine and characterize the vibration signal of the gear system.

4) A parametric study of the effects on the vibration signal due to various changes in the gear mesh stiffness model, simulating various degrees of pitting and wear damage, could provide a comprehensive database for gear fault detection and damage estimation research.
CHAPTER 6

QUANTIFICATION OF GEAR TOOTH DAMAGE

BY OPTIMAL TRACKING OF VIBRATION SIGNATURE

6.1. Objective

In the last two decades, with demands for higher operating speeds and greater load capacity, premature failures in high-performance turbomachinery have often resulted in enormous financial losses and, at times, catastrophic consequences. In aeronautical applications, where both weight and efficiency are pushed to their design limits, the prevention and management of premature equipment failures is a vital part of the maintenance program. Current onboard condition-monitoring systems for gas turbine engines often fail to provide sufficient time between warning and failure for safety procedures to be implemented. On the other hand, inaccurate interpretation of operating conditions may result in false alarms and unnecessary repairs and downtime. The early detection of incipient failure in a mechanical system is of great practical importance as it permits scheduled inspections without costly shutdowns and indicates the urgency and locations for repair before a system incurs catastrophic failure.

Some success has been achieved in identifying damage in a gear transmission system by using the Wigner-Ville distribution (WVD) technique as described in the previous chapters [4,7,9,15]. The approach is to use statistical pattern recognition to match the WVD signature patterns of damaged gears with standard patterns stored in a data base. Although the WVD technique is useful for determining the type and location of the damage, it is not much help in quantifying the level of damage. Damage quantification would logically be the next step in
failure prediction; however, no explicit attempts at damage quantification have previously appeared in the literature.

This chapter presents a new technique for processing vibration data to quantify the level of damage in a gear transmission system. The technique consists of a nonlinear numerical optimization in the form of an “optimal tracking” problem [56,57]. The optimization uses a dynamic model of the gear mesh and forms an estimate of the time-varying mesh stiffness that best corresponds to the given set of vibration data. The utility of the technique relies on the relationship between the wear or damage of a gear tooth and the change in stiffness of the mesh during a given tooth pass cycle. An analysis of this relationship demonstrates that the perturbation of the stiffness function from the nominal profile can be used to quantify the level of damage.

The optimal tracking technique for estimating the perturbation of the mesh stiffness was tested in two settings. First, it was tested on a set of fictitious data generated by computer simulation of a one-degree-of-freedom mechanical system with time-varying stiffness. The solution of the optimal tracking problem matched very closely the actual stiffness profile used in the model generating the data. Then, the technique was tested on a set of experimental data from a gear test rig, but still assuming the one-degree-of-freedom model. Despite the simplicity of the model the stiffness profile obtained was shown to be useful in correlating to the level of damage of the gear transmission system.

This chapter is organized as follows: Section 2 presents the system model and formulates the optimal tracking problem. Section 3 outlines the numerical solution procedure for the
nonlinear optimization. Section 4 presents and interprets the results of the optimization and discusses the next steps to be taken in developing a comprehensive failure-prediction procedure.

6.2. OPTIMAL TRACKING PROBLEM

6.2.1 System Model

The system considered in this study consisted of a small pinion in mesh with a larger gear. A simple model of this system has the two gear masses connected by a spring and a damper. The larger gear is much heavier than the pinion; hence, it is assumed to be rigid, so that all relative motion between the two is attributed to the motion of the pinion. Then, the equation of motion of the pinion takes the form

\[ m\ddot{x} + c\dot{x} + k(t)x = 0 \]  \hspace{1cm} (6.1)

where \( m \) is the mass of the pinion and \( k(t) \) and \( c \) are the stiffness and damping of the mesh. The mesh stiffness is not constant but is nominally a periodic function of the gear angle, with each period corresponding to one tooth pass. The high points on the periodic stiffness function correspond to gear angles where two pairs of gear teeth are in contact, and the low points correspond to angles where only one pair is in contact.

It has been found in experiments on gearbox vibrations[7-9] that the gear mesh stiffness changes with the wear, pitting, or fracture of the gear teeth. Such changes in the gear mesh stiffness inevitably lead to changes in the vibration signatures of the mechanical system. The objective of the optimal tracking procedure developed in this study is to reconstruct the true stiffness profile for a damaged gear tooth from the measured vibration. That is, the objective is to
determine the function $k(t)$ that would result in the measured vibration according to the system model (6.1).

The true stiffness profile can be expressed as the sum of a constant (time averaged) component, a nominal periodic component, and a perturbation resulting from gear wear or damage. Accordingly, the system model (6.1) is written as

$$m\ddot{x} + c\dot{x} + [k_{ave} - k_{periodic} - k_{perturb}(t)]x = 0,$$

or

$$\ddot{x} + \frac{c}{m}\dot{x} + \Omega^2 x = u(t)x,$$

where $\Omega^2 = k_{ave}/m$ and $u(t)$ represents the total time-varying component of the stiffness divided by the pinion mass. By defining the variables

$$x_1 = \dot{x}, \quad x_2 = x,$$

the system model can be written in the state-variable form

$$\begin{align*}
\dot{x}_1 &= -\frac{c}{m}x_1 - \Omega^2 x_2 + u(t)x_2 \\
\dot{x}_2 &= x_1
\end{align*}$$

with the given initial conditions

$$x_1(t_0) = \dot{x}_0, \quad x_2(t_0) = x_0.$$

### 6.2.2 Optimization Problem

Suppose that a data set corresponding to the vibration of the pinion is collected over the interval $[t_0, t_f]$. Let the function describing the data set be denoted as $\ddot{x}_2(t)$, since it corresponds to
the modeled variable \( x_2(t) \). The objective is to determine a reasonable time-varying stiffness component \( u(t) \) for which the model output \( x_2(t) \) approximates the measured data \( \bar{x}_2(t) \).

A diagram depicting the functional objective is shown in Fig. 60. In the figure \( u(t) \) is depicted as an input to be chosen so that the error \( e(t) \) will be small for all time. Note that this problem has the form of a tracking problem, where the control input of a system is designed so that the system output follows a prescribed reference function. Such a problem may be approached by using the standard techniques of optimal control theory\[56,57\]. In particular, the "design" of a suitable function \( u(t) \) may be achieved by minimizing the quadratic cost functional

\[
J = \frac{1}{2} \beta_f \left( x_2(t_f) - \bar{x}_2(t_f) \right)^2 + \frac{1}{2} \int_0^{t_f} \left( \beta_1 (x_2(t) - \bar{x}_2(t))^2 + \beta_2 u^2(t) \right) dt,
\]

where \( \beta_1, \beta_2, \) and \( \beta_f \) are cost-function weighting coefficients. This form of the cost functional penalizes the energy in the error between the modeled output and the measured data. It also penalizes the use of too large a stiffness perturbation function in order to avoid singularity in the solution.

In the optimal tracking problem the system dynamic equations (6.5) are treated as equality constraints imposed in the optimization of the cost (6.7). As such, they are appended to the cost function by using time-varying Lagrange multipliers \( \lambda_1(t) \) and \( \lambda_2(t) \). These Lagrange multipliers are themselves governed by differential equations called the costate equations. The costate equations together with the state equations of the system model form a two-point boundary value problem (TPBVP)\[56,57\]. The TPBVP equations are

\[
\begin{align*}
\dot{x}_1 &= -\frac{c}{m} x_1 - \Omega^2 x_2 + u(t)x_2 \\
\dot{x}_2 &= x_1
\end{align*}
\]

(State equations)
The TPBVP (6.8–6.12) represents a set of necessary conditions for \( u(t) \) to be the solution of the optimal tracking problem. The TPBVP consists of a set of four coupled differential equations (6.8–6.9), together with an algebraic relation (6.10), and some endpoint conditions (6.11–6.12) at both \( t_0 \) and \( t_f \). Notice that the TPBVP is nonlinear: the unknown function \( u(t) \) multiplies other independent variables in the differential equations.

6.3. NUMERICAL SOLUTION PROCEDURE

The nonlinear TPBVP (6.8–6.12) is solved by an iterative procedure. A complete and general derivation of the procedure is given in Sage[57] and Dyer and McReynolds [55]. Some of the salient points are outlined below for convenience.

6.3.1 Successive Sweep Method

Solving the nonlinear TPBVP requires an iterative method. Although several approaches are possible, a common and useful one is to begin with an initial guess \( u^0(t) \) and use it to integrate the nonlinear state equations (6.8) forward in time starting from the initial conditions (6.11) to determine the nominal state functions \( x^0_1(t) \) and \( x^0_2(t) \). Then, starting from the final conditions (6.12), integrate the nonlinear costate equations backward in time to determine the
nominal costate functions $\lambda_1^0(t)$ and $\lambda_2^0(t)$. The nominal functions $u^0(t)$, $x_1^0(t)$, $x_2^0(t)$, $\lambda_1^0(t)$, and $\lambda_2^0(t)$ then satisfy all the TPBVP equations except the stationarity condition (6.10).

The nominal state, costate, and input functions must be iteratively updated, so that they will eventually satisfy all the nonlinear TPBVP equations, including the stationarity condition. Each update is accomplished by solving a linearized version of the TPBVP. A standard method for doing this is known as the sweep method, whereby a linear relationship between the state and costate functions is assumed. Then, the linear TPBVP degenerates into a set of ordinary differential equations with endpoint conditions at the final time only. These are solved by a straightforward numerical integration. In the case of the optimal tracker these ordinary differential equations take the form of the coupled Riccati equations

\[
\begin{align*}
\dot{p}_{11} &= 2 \left( \frac{c}{m} p_{11} - p_{12} \right) + p_{11}^2 \frac{x_2^2}{\beta_2} \\
\dot{p}_{12} &= \frac{c}{m} p_{12} - p_{22} - p_{11} \left( -\Omega^2 + u(t) - \frac{1}{\beta_2} \lambda_1 x_2 \right) + p_{11} p_{12} \frac{x_2^2}{\beta_2} \\
\dot{p}_{22} &= -2p_{12} \left( -\Omega^2 + u(t) - \frac{1}{\beta_2} \lambda_1 x_2 \right) + p_{12}^2 \frac{x_2^2}{\beta_2} - \left( \beta_1 + \frac{\lambda_1}{\beta_2} \right)
\end{align*}
\]  

(6.13)  

with endpoint conditions

\[
P_{11}(t_f) = p_{12}(t_f) = 0, \quad p_{22}(t_f) = \beta_f
\]  

(6.14)

together with the auxiliary linear equations

\[
\begin{align*}
\dot{h}_1 &= h_1 \left( \frac{c}{m} + p_{11} \frac{x_2^2}{\beta_2} \right) - h_2 - p_{11} \varepsilon \frac{x_2^2}{\beta_2} (\lambda_1 x_2 + \beta_2 u(t)) \\
\dot{h}_2 &= -h_1 \left( -\Omega^2 + u(t) - \frac{1}{\beta_2} \lambda_1 x_2 - p_{12} \frac{x_2^2}{\beta_2} \right) - \frac{\varepsilon}{\beta_2} (\lambda_1 x_2 + \beta_2 u(t))(p_{12} x_2 + \lambda_1)
\end{align*}
\]  

(6.15)
with the endpoint conditions

\[ h_1(t_f) = h_2(t_f) = 0. \]  \hfill (6.16)

Note that the \( x \) and \( \lambda \) variables in the differential equations (6.13) and (6.15) represent the given nominal functions. (The zero superscripts have been omitted for convenience.) They are simply treated as time-varying coefficients in the numerical integration of the differential equations. The solutions of equations (6.13) and (6.15) are then used to compute the corrections to the nominal state, costate, and input functions. This computation requires yet another numerical integration, this time of the linearized state equations

\[
\begin{align*}
\Delta \dot{x}_1 &= -\Delta x_1 \left( \frac{c}{m} + p_{11} \frac{x_2^2}{\beta_2} \right) + \Delta x_2 \left( -\Omega^2 + u(t) - \frac{1}{\beta_2} \lambda_1 x_2 - p_{12} \frac{x_2^2}{\beta_2} \right) - \\
&\quad - h_1 \frac{x_2^2}{\beta_2} + \varepsilon \frac{x_2}{\beta_2} (\lambda_1 x_2 + \beta_2 u(t)) \\
\Delta \dot{x}_2 &= \Delta x_1
\end{align*}
\]  \hfill (6.17)

with the zero initial conditions

\[ \Delta x_1(t_0) = \Delta x_2(t_0) = 0. \]  \hfill (6.18)

Finally, the update of the nominal control is computed as

\[
\Delta u = \varepsilon \frac{\lambda_1 x_2 + \beta_2 u(t)}{\beta_2} - \frac{1}{\beta_2} (\lambda_1 \Delta x_2 + x_2 (p_{11} \Delta x_1 + p_{12} \Delta x_2 + h_1)),
\]  \hfill (6.19)

where \( \varepsilon \) is the step size, and the new nominal control is given by

\[ u^{i+1}(t) = u^i(t) + \Delta u^i(t). \]  \hfill (6.20)
(The superscripts $i$ and $i+1$ denoting the iteration number have been reinserted in equation (6.20).) The procedure is repeated until the nominal functions converge to a solution.

The real scalar $\varepsilon \in [0,1]$ in equations (6.15), (6.17), and (6.19) is used as a "step size" parameter. Using a smaller value of $\varepsilon$ tends to decrease the magnitudes of the corrections, thereby improving the stability of the iterative procedure but slowing the convergence to the solution. Using a larger value of $\varepsilon$ has the opposite effects.

### 6.3.2 Numerical Details

The choices of the cost-function weighting coefficients $\beta_1$, $\beta_2$, and $\beta_f$ are important for effective numerical optimization. The parameter $\beta_1$ defines the penalty on the difference between the calculated and reference vibration signals. Since the goal is to minimize the difference between the calculated and tracked vibration signals, a large weighting coefficient $\beta_1$ should be chosen. The parameter $\beta_2$ defines the penalty on the function $u(t)$. Generically speaking, $\beta_2$ should impose a lighter penalty on $u(t)$ than $\beta_1$ imposes on the tracking error. Note also that the choice of units has an effect on the appropriate relative sizes of $\beta_1$ and $\beta_2$. In the examples studied the numerical values of $u(t)$ are considerably larger in magnitude than those of a reasonable vibration-signal error; therefore, even if equal weighting between error and control were desired, $\beta_2$ should be chosen to be considerably smaller than $\beta_1$. An inappropriately large choice of the parameter $\beta_2$ would make the cost function almost unchanged from one iteration to the next. Thus, a small constant value was chosen for the parameter $\beta_2$. The parameter $\beta_f$ defines
the penalty for the error at the final time. If $\beta f$ is too small, a large vibration error at the final time will result.

By following these general guidelines the optimization algorithm described in the previous section was realized in a computer program. The equations were integrated with a seventh-order Runge-Kutta-Fehlberg method. A summary of the programming steps is given below:

0. Set $i = 0$ and take the initial guess $u^0(t)$ for the function $u(t)$ to be zero.

1. Using the function $u^i(t)$ from the previous step, integrate the state equations (6.8) forward in time. Calculate the resulting cost function $J^i$.

2. Integrate the costate equations (6.9) backward in time.

3. Use the computed state and costate variables as time-varying coefficients in the integration of the Riccati equations (6.13) along with the auxiliary equations (6.15) backward in time.

4. Integrate the linearized state equations (6.17) forward in time. Using the linearized stationarity condition (6.19), calculate the correction $\Delta u^i(t)$ to the nominal function $u^i(t)$ and hence the updated function $u^{i+1}(t)$. Also, calculate the new cost function $J^{i+1}$.

5. Make decisions about the continuation of the optimization procedure and the choice of the parameters:
   
   a. If the difference between the calculated and tracked vibration signals is small, the optimization procedure is finished.
   
   b. If the difference $J^{i+1} - J^i < 0$ is large enough, repeat from step 1.
   
   c. If the difference $J^{i+1} - J^i < 0$ is too small, increase the weighting $\beta_1$ and repeat from step 1.
d. If $J_{i+1} > J_i$, repeat from step 1 using a smaller value of the step size $\varepsilon$. If this is not successful, increase the error weighting $\beta_1$ and repeat from step 1.

Some comments should be made on step 5 of the numerical procedure. It was observed that for given values of weighting coefficients and the step-size parameter the optimization procedure converges to some value of the cost function. In this case the difference between the values of the cost functions $J_{i+1} - J_i$ becomes negligible after some iterations. This means that the cost associated with the control $u(t)$ is becoming dominant. Therefore, it makes sense to start a new iteration with an increased weight $\beta_1$ (i.e., imposing a higher penalty on the vibration error).

6.4. DISCUSSION OF RESULTS

To demonstrate the optimal tracking procedure described above, two numerical cases were used in this study. The first case was a numerical experiment in which the tracker was applied to a set of vibration signals generated numerically, assuming a given gear mesh stiffness profile. The mesh stiffness profile evaluated by the optimal tracker was compared with the original stiffness used in generating the vibration signal. Figure 61(a) shows the comparison between the vibration signal generated by a sinusoidal stiffness and that simulated by the optimal tracker. As shown in the figure the two vibration signals were very similar; the small difference between the two signals is given in Fig. 61(b). Figure 62(a) depicts the original gear mesh stiffness used and the stiffness evaluated by using the optimal tracker; the difference between the two stiffnesses is given in Fig. 62(b). The excellent agreement between the two stiffnesses in this
numerical experiment has confirmed the applicability of the optimal tracking procedure in evaluating system stiffness changes from system vibration signals. However, this close resemblance between the generated and simulated signals was partly due to the original time signals being smooth, continuous, and harmonic without any substantial change in magnitude and phase over the gear revolution. To demonstrate the generality and limitation of the developed procedure, a set of experimental data taken from a test rig was used in the next case.

The second case was based on the experimental data obtained from the spiral bevel gear test rig shown in Fig. 63. The primary purpose of this rig is to study the effects of gear tooth design, gear materials, and lubrication types on the fatigue strength of aircraft-quality gears [45]. Because spiral bevel gears are used extensively in helicopter transmissions to transfer power between nonparallel intersecting shafts, using this fatigue rig for diagnostic studies is extremely practical. Vibration data from an accelerometer mounted on the pinion shaft bearing housing were captured by using a personal computer with an analog-to-digital conversion board and an anti-aliasing filter. The 12-tooth test pinion and the 36-tooth gear have the following characteristics: 0.5141 in pitch, 35° spiral angle, 1-in. face width, 90° shaft angle, and 22.5° pressure angle. The pinion transmits 720 hp at a nominal speed of 14 400 rpm. The test rig was started and stopped several times for gear damage inspection. The test was ended at 17.72 operational hours when a broken portion of a tooth was found visually during one of the shutdowns.

Figure 64(a) depicts the gear tooth after 6.5 hr of operation. Note that there is heavy surface pitting on one gear tooth with minor pitting on the next tooth. Figure 64(b) shows the time domain averaging, the frequency spectrum, and the joint time-frequency analysis using the

Figure 65. Simulated gear tooth wear and corresponding gear stiffness (a) Simulated gear tooth wear L2:L1 = percent engagement profile wear. (b) Gear stiffness calculated from simulated tooth wear.
Wigner-Ville distribution (WVD) [4,7-9,15] of the accelerometer signal at 6.5 hr[9]. Note that in Fig. 64(b) the time signal indicates a large vibratory signal during the engagement of the sixth and seventh teeth (damaged teeth), but the frequency spectrum, because of its averaging characteristics, shows very little change from the original signal [9]. The WVD begins to show a pattern of shifting of the major frequency component (at a mesh frequency of 2880 Hz) around the meshing of the sixth and seventh teeth. The WVD pattern in this case is very similar to those resulting from a short-term amplitude and phase change of a vibration signal. Although it has been established by the authors in some previous publications [7-9] that such damage in the gear can be identified by the WVD pattern recognition process, the level of the damage has not been addressed. A recent study by the authors has shown that wear and surface pitting of the gear tooth usually will result in a phase shift in the stiffness profile, without any significant change in the stiffness magnitude. Figure 65 shows the stiffness change in a gear mesh evaluated [10] from gear tooth surface profile variations. Note in Fig. 65(b) that increasing surface profile variation increases the phase shift of the gear stiffness without changing the magnitude of the stiffness.

Incorporating this constant gear mesh stiffness as an additional constraint, the optimal tracking procedure was applied to the experimental vibration signal (obtained from the bevel gear test rig at 6.5 hr as shown in Fig. 64) to evaluate the corresponding gear mesh stiffness. To better evaluate the gear mesh stiffness, the time signal was filtered at a mesh frequency of 2880 Hz. Figure 66(a) shows the comparison between the unfiltered experimental signal and the optimal tracker simulation, and Fig. 66(b) shows the comparison between the filtered experimental signal and the tracker-simulated signal. Note that because of the substantial change of magnitude and phase of the time signal during the data acquisition period (one revolution of the gear), the
Figure 66 - Filtered and unfiltered experimental and tracker simulated vibration signals for spiral bevel gear at 6.5 hr. (a) Unfiltered. (b) Filtered.

Figure 67 - Tracker evaluated mesh stiffness for spiral bevel gear at 6.5 hr.
accuracy in the simulated vibration is not as good as that in the numerical experiment (Fig. 61(a)). Figure 67 depicts the gear mesh stiffness evaluated by using the optimal tracker. Note that in the evaluated stiffness considerable phase shifts at several gear teeth resulted in the large variation in magnitude and phase of the vibration signal. At the location where pitting occurred (teeth 6 and 7) the phase shift of the stiffness was more pronounced. By using the results from the evaluated mesh stiffness and the correlation of stiffness change with gear wear shown in Fig. 65(b), the gear damage can be estimated.

6.5. CONCLUSIONS

This chapter presents a unified approach to identifying and quantifying damage in a gear transmission system. The conclusions from this study are as follows:

1. The application of the joint time-frequency technique called the Wigner-Ville distribution provides the ability to identify the types and locations of the gear damage.

2. The optimal tracker developed in this chapter provides a very reasonable estimate of the stiffness change due to damage, which can be related to the level of gear damage.

3. For vibratory signals with large changes in magnitude and phase angle the accuracy of the simulated signal from the optimal tracker may decrease.

4. For a more accurate evaluation of system mesh stiffness an optimal tracker for the complete dynamic model of the system is needed.
CHAPTER 7

GENERAL CONCLUSIONS

During this study, a numerical procedure has been developed to simulate the dynamics of gear transmission systems with the effects of gear tooth damage due to wear and pitting. The numerical procedure developed consists of (a) a numerical model to simulate the gear mesh stiffness change resulting from gear tooth damage due to surface pitting and wear, (b) a modal synthesis methodology to simulate the dynamics of gear transmission systems, (c) a joint time-frequency analysis using the Wigner-Ville distribution (WVD) method to provide a comprehensive representation of the vibration signature for fault detection, and (d) the use of an optimal tracker to quantify the damage in the gear tooth. The developed numerical procedure was verified by comparison with vibration data from a damaged gear obtained at the NASA Lewis Research Center. The specific accomplishments in this project can be summarized as follows:

1. A method has been developed to simulate the effects of tooth surface wear in a gear transmission system. The tooth surface wear level can be controlled by adjustment of both amplitude and length in the tooth profile modification.

2. Using the developed gear tooth damage model, tooth damage due to wear and pitting can be simulated by amplitude and phase changes in the gear mesh stiffness model. The gear mesh model developed can easily be incorporated into the global transmission system for dynamic predictions.

3. A numerical procedure has been developed to simulate the vibration in a gear transmission system with effects of gear tooth damage due to wear and pitting. The modal synthesis methodology was used for simulating the dynamics of gear transmission systems. The gear
mesh model developed to simulate the gear tooth damage due to wear and pitting are incorporated numerically into the global system for dynamics predictions.

4. The Wigner-Ville distribution (WVD) method used for the joint time-frequency analysis provides a comprehensive representation of the vibration signal. It was successfully used to verify the numerical model developed.

5. Based on the results of the application of the various time and frequency analysis techniques, it can be concluded that the WVD provides vital information concerning both the severity and the location of the pitting process in the gear system. The fracture of the gear tooth and its exact location can be pinpointed using the WVD technique. However a machine vibration signature database is required to interpret the resulting WVD.

6. A parametric study of the effects on the vibration signal due to various degrees of pitting and wear damage, has provided a comprehensive database for gear fault detection and damage estimation research.

7. A parametric study of the effects on the vibration signal due to various changes in the gear mesh stiffness model, simulating various degrees of pitting and wear damage, could provide a comprehensive database for gear fault detection and damage estimation research.

8. The optimal tracker developed in this chapter provides a very reasonable estimate of the stiffness change due to damage, which can be related to the level of gear damage. For vibratory signals with large changes in magnitude and phase angle the accuracy of the simulated signal from the optimal tracker may decrease. For a more accurate evaluation of system mesh stiffness an optimal tracker for the complete dynamic model of the system is needed.
