Origin of ozone and NOx in the tropical troposphere: A photochemical analysis of aircraft observations over the South Atlantic basin

Abstract. The photochemistry of the troposphere over the South Atlantic basin is examined by modeling of aircraft observations up to 12-km altitude taken during the TRACE A expedition in September-October 1992. A close balance is found in the 0 to 12-km column between photochemical production and loss of O3, with net production at high altitudes compensating for weak net loss at low altitudes. This balance implies that O3 concentrations in the 0-12 km column can be explained solely by in situ photochemistry; influx from the stratosphere is negligible. Simulation of H2O2, CH3OOH, and CH2O concentrations measured aboard the aircraft lends confidence in the computations of O3 production and loss rates, although there appears to be a major gap in current understanding of CH2O chemistry in the marine boundary layer. The primary sources of NOx over the South Atlantic Basin appear to be continental (biomass burning, lightning, soils). There is evidence that NOx throughout the 0 to 12-km column is recycled from its oxidation products rather than directly transported from its primary sources. There is also evidence for rapid conversion of HNO3 to NO2 in the upper troposphere by a mechanism not included in current models. A general representation of the O3 budget in the tropical troposphere is proposed that couples the large-scale Walker circulation and in situ photochemistry. Deep convection in the rising branches of the Walker circulation injects NOx from combustion, soils, and lightning to the upper troposphere, leading to O3 production; eventually, the air subsides and net O3 loss takes place in the lower troposphere, closing the O3 cycle. This scheme implies a great sensitivity of the oxidizing power of the atmosphere to NOx emissions in the tropics.

1. Introduction

Ozone in the tropical troposphere plays a key role in determining the global oxidizing power of the atmosphere. Most of the oxidation of long-lived gases by OH takes place in the tropics, where high UV and humidity promote the formation of OH from photolysis of O3 [Logan et al., 1981; Thompson, 1992]. Ozone is produced within the troposphere by photochemical oxidation of hydrocarbons and CO in the presence of nitrogen oxides (NOx = NO + NO2) and is also transported down from the stratosphere.

There is continuing controversy as to the relative importance of tropospheric production versus stratospheric influx in controlling O3 concentrations in the troposphere, including in the tropics [Liu et al., 1980; Levy et al., 1985; Logan and Kirchhoff, 1986; Krishnamurti et al., 1993; Dibb et al., 1996; Graustein and Turkstian, 1996; Browell et al., this issue; Loring et al., this issue]. There is also considerable uncertainty regarding the origin of NOx, the limiting precursor for O3 production in the troposphere [Levy and Moosin, 1989; Penner et al., 1991; Kasibhatla et al., 1991, 1992]. We examine here the origin of O3 and NOx in the tropical troposphere using observations made during the TRACE A aircraft expedition in September-October 1992 [Fishman et al., this issue]. This expedition provided a detailed survey of O3 and its precursors over the tropical South Atlantic and neighboring continents up to 12-km altitude. Its primary objective was to identify the cause of the large-scale O3 enhancement observed in the region during the austral spring dry season [Fishman et al., 1990]. Results from TRACE A confirmed earlier suggestions that this enhancement is caused by seasonal biomass burning emissions of NOx, hydrocarbons, and CO from southern Africa and South America [Logan and Kirchhoff, 1986; Fishman et al., 1990; Anderson et al., 1993; Andreae et al., 1994; Gregory et al., this issue; Kirchhoff et al., this issue; Olson et al., this issue; Thompson et al., this issue].

Our goal in the present paper is to explain the total tropospheric O3 column observed in TRACE A, not just the biomass burning enhancement, and to draw general inferences regarding the budget of O3 in the tropical troposphere. As pointed out by
Thompson et al. [this issue], the tropospheric O₃ column over the South Atlantic during the dry season maximum is only 50% higher than the wet season background when biomass burning influence is minimal. This O₃ background, over the South Atlantic and elsewhere in the tropical troposphere, plays a critical role in determining the oxidizing power of the atmosphere.

Our analysis is based on a combination of photochemical modeling and statistical interpretation of the TRACE A data. The modeling approach is described in section 2 and is evaluated in sections 3 and 4 by simulation of H₂O₂, CH₃OOH, and CH₂O concentrations measured aboard the aircraft. Regional budgets for O₃ and NOₓ over the South Atlantic basin are derived in sections 5 and 6, respectively. A general representation of the O₃ budget in the tropical troposphere is proposed in section 7. Conclusions are in section 8.

2. Modeling Approach

The TRACE A expedition used a DC-8 aircraft with a ceiling of 12-km altitude. The southern hemisphere flight tracks (Figure 1) covered the tropical South Atlantic, eastern Brazil, and southern Africa; we refer to this region as the "South Atlantic basin." Details on the flights and references for the observations are given by Fishman et al. [this issue]. Measurements aboard the aircraft included concentrations of O₃, CO, NO, peroxyacetyl-nitrate (PAN), peroxypropionylnitrate (PPN), HNO₃, speciated hydrocarbons, acetone, H₂O₂, CH₃OOH, CH₂O, and organic acids. Meteorological variables, UV fluxes, and aerosol number size distributions were also measured. Table 1 gives median values for the various measurements at different altitudes.

We base our analyses on merged time series of the aircraft data where all measurements have been averaged over a common time interval. The choice of averaging interval must balance the need for high temporal resolution with the danger of misinterpret-

![Figure 1. TRACE A flight tracks (September 23 - October 25, 1992). Flight numbers are indicated. The region covered by the southern hemisphere flight tracks is referred to in the paper as the South Atlantic basin.](image)

| Table 1a. Median Measured Values Over the South Atlantic Basin During TRACE A |
|---------------------------------|-----------------|-----------------|-----------------|
| Altitude                        | 0-4 km          | 4-8 km          | 8-12 km         |

Statistics are for the ensemble of southern hemisphere data collected in TRACE A. The median concentrations of >C₅ alkanes, >C₃ alkenes, xylenes, isoprene, and terpenes were below the detection limit of 2 pptv. Concentrations of NO₂ were measured in TRACE A, but the measurement is considered unreliable [Crawford et al., 1996] and is not used in the paper.

*oa* Measured with an Eppley radiometer (Eppley, Inc., Newport, Rhode Island).
ing coarse-resolution data. We choose to average the data over the sampling time of the critical variable with the coarsest time resolution. Because this critical variable depends on the problem at hand, we will use the course of this paper four different merged time series matched to the sampling times of peroxides, CH3O, NO, and HNO3 (Table 2). Ozone columns are included in the merged time series using daily observations with 1°x1.25° resolution from the total ozone mapping spectrometer (TOMS). The median O3 column over the south tropical Atlantic during TRACE A was 281 Dobson units (DU) (1 DU = 2.687x10^{16} molecules cm^{-2}).

A major objective of this paper is to derive a chemical budget for O3 in the tropospheric column over the South Atlantic basin (section 5). Our approach is to calculate 24-hour average O3 production and loss rates for individual points in the merged time series of aircraft data and to use statistics from the ensemble of points to infer regionally averaged rates. Rapid chemical cycling takes place between Oa and other members of the odd-oxygen family (Oa = O3 + O + NO2 + HNO4 + (2x)NO3 + peroxoacetyl nitrates), hence the budget analysis must be based on Oa rather than on O3. Considering that Ox accounts typically for over 99% of Oa, the budgets of O3 and Oa can be viewed as equivalent. Production of Oa is mainly by reactions (1) and (2):

\[ \text{HO}_2 + \text{NO} \rightarrow \text{OH} + \text{NO}_2 \]  
\[ \text{RO}_2 + \text{NO} \rightarrow \text{RO} + \text{NO}_2 \]

where RO2 is any organic peroxy radical (CH3O2 is the most important). Loss of Oa is principally by reactions (3)-(5):

\[ \text{O}_3 + \text{hv} \rightarrow \text{O}_2 + \text{O}^3 \text{D} \]  
\[ \text{O}^3 \text{D} + \text{H}_2\text{O} \rightarrow 2\text{OH} \]

Calculation of O3 production and loss rates requires knowledge of the concentrations of HO3 radicals (OH, HO2, RO2) along the flight tracks. These species were not measured from the aircraft. We estimate their concentrations for each point in the merged time series by using a zero-dimensional photochemical model constrained with the ensemble of measurements for that point (Table 3). The model is described in Appendix A. It calculates the diel steady state concentrations of HO3 radicals, short-lived NOx species (NO, NO2, NO3, N2O5, HNO2, HNO3, organic nitrates), and other photochemical intermediates (peroxides, carbonyls). Production and loss of species are by chemical reactions only (loss by deposition is not considered). "Diel steady state" is defined by reproducibility of concentrations over a 24-hour solar cycle, as obtained in a time-dependent calculation with periodic boundary conditions

\[ C_i(t) = C_i(t + T) \]

where \( C_i \) is the concentration of species \( i \), \( t \) is time, and \( T = 24 \) hours. In this calculation, all input variables in Table 3 except NO are assumed constant over the diel cycle. The concentration of NO must be calculated as a time-dependent quantity because of the strong diel variation driven by photochemical steady state with NOx. The few available observations in the remote troposphere indicate little diel variation of NOx [Carroll et al., 1992], but some variation might be expected in the upper troposphere due to cycling with HNO4. We assume in the model that the concentration of NOx (NO + NO2 + NO3 + (2x)N2O5 + HNO2 + HNO3) is constant over the diel cycle and calculate its value within the model to match the observed NO concentration at the time of day of the measurement.

| Table 1b. Median Model Values Over the South Atlantic Basin During TRACE A |
|--------------------------|---------------|---------------|
|                          | 0-4 km        | 4-8 km        | 8-12 km       |
|--------------------------|---------------|---------------|
| OH, 10^3 cm^-3           | 27            | 16            | 12            |
| HO2, 10^3 cm^-3          | 257           | 96            | 22            |
| CH3O2, 10^3 cm^-3        | 103           | 34            | 1             |
| NOx=NO+NO2, pptv         | 73            | 57            | 145           |
| HNO3, pptv               | 1             | 10            | 54            |

Twenty-four hour average model values computed as described in section 2. The concentration of NOx is calculated in the model using as constraint the NO measurement for the time of day of observation.

Each data point represents one measurement time interval for the matched species. Model points are the subset of data points for which photochemical model quantities can be computed: the computation requires that data for all variables in Table 3 be available for at least a fraction of the time interval. We also give in parentheses the number of model points obtained in the fixed-hydrocarbon approximation, which relaxes the constraint on availability of data for hydrocarbons and acetone (see section 2).

4 The total O3 column is distributed vertically using the mean O3 profiles measured by ozonesondes at Ascension Island and southern Africa during TRACE A [Thompson et al., 1995].

5 The cloud correction factor (CF) is calculated from the UV flux observations as described in Appendix A.

6 The model calculation assumes a constant concentration of NOx (NOx = NO + NO2 + NO3 + (2x)N2O5 + HNO2 + HNO4) over the diel cycle and adjusts the concentration of NOx to match the observed NO concentration at the time of day of observation.

7 Data for HNO3 and PAN are required only for the NOx budget calculation of section 6. For other applications, if HNO3 data are unavailable then a low value is assumed; and if PAN data are unavailable, then PAN concentrations are assumed from chemical steady state. These assumptions greatly increase the number of data points at which model calculations can be done without inducing significant error in the relevant model output quantities.

8 If data are not available for these variables, default values are used of 1.7 ppmv for CH4 and zero for formic acid, acetic acid, and aerosol number concentrations.

9 See Table 1a for size class information.

Concentrations of H2O2, CH3OOH, and CH2O are calculated in the model, rather than constrained from observations, and comparison of simulated versus observed values serves to test the model (sections 3 and 4). These three species are sensitive to different aspects of HOx chemistry [Heikes, 1992; Liu et al., 1992]. Hydrogen peroxide is particularly valuable as a test of O3 production in the model because its source,

\[ \text{HO}_2 + \text{HO}_2 \rightarrow \text{H}_2\text{O}_2 + \text{O}_2 \]  (7)

varies quadratically with the concentration of HO2, the principal peroxy radical responsible for O3 production. At low altitudes where H2O2 is the principal sink of HO2, the concentration of H2O2 reflects the rate of the O(1D)+H2O reaction which is the principal source of HO2 and the principal sink of O3.

We will also apply the model to study the chemical cycling of NOx over the South Atlantic basin in light of the concurrent measurements of NOx, HNO3, and PAN made aboard the aircraft (section 6). Oxidation of NOx to HNO3 and PAN takes place on a timescale of the order of 1 day:

\[ \text{NO}_2 + \text{OH} + \text{M} \rightarrow \text{HNO}_3 + \text{M} \]  (8)

\[ \text{NO}_2 + \text{O}_3 \rightarrow \text{NO}_3 + \text{O}_2 \]  (9a)

\[ \text{NO}_3 + \text{NO}_2 + \text{M} \rightarrow \text{N}_2\text{O}_5 + \text{M} \]  (9b)

\[ \text{N}_2\text{O}_5 \stackrel{\text{aerosol,H}_2\text{O}}{\rightarrow} 2\text{HNO}_3 \]  (9c)

\[ \text{NO}_3 + \text{CH}_2\text{CO}_3 + \text{M} \rightarrow \text{PAN} + \text{M} \]  (10)

Organic nitrates other than PAN are also formed but represent only minor sinks for NOx in the model. The species HNO3 and PAN can act as reservoirs for NOx, decomposing to release NOx far from its point of origin:

\[ \text{HNO}_3 + \text{hv} \rightarrow \text{NO}_2 + \text{OH} \]  (11)

\[ \text{HNO}_3 + \text{OH} \rightarrow \text{NO}_3 + \text{H}_2\text{O} \]  (12a)

\[ \text{NO}_3 + \text{hv} \rightarrow \text{NO}_2 + \text{O}_3 \]  (12b)

\[ \text{PAN} \stackrel{\text{heat}}{\rightarrow} \text{NO}_2 + \text{CH}_3\text{CO}_3 \]  (13)

\[ \text{PAN} + \text{hv} \rightarrow \text{NO}_2 + \text{CH}_2\text{CO}_3 \]  (14)

We compute the 24-hour average rates of reactions (8)-(14) in the model at individual points using the observed concentrations of NO, HNO3, and PAN as constraints, as discussed above. The resulting mass balance between sources and sinks of NOx allows us to estimate the degree to which NOx concentrations are maintained by chemical recycling from HNO3 and PAN through the above set of reactions. In such a NOx budget calculation it is necessary to correct the rates of conversion between NOx and PAN to account for cycling within the (CH3CO3+PAN) family; the correction is described in Appendix B.

Table 1b gives the median concentrations of OH, HO2, CH3O, CH2O, NOx, and HNO3 computed in the model for the southern hemisphere TRACE A data set. Diel steady state for these species and for CH2O is typically approached to within 10% after 2 days of integration in the model. The peroxydes, which have longer lifetimes, require typically 2-3 days at 2 km and 1 week at 8-12 km for approach to steady state. The steady state assumption is prone to large errors in pollution plumes and in the continental boundary layer, where concentrations of the input variables in Table 3 may change greatly over timescales of less than 1 day. It is more adequate in the free troposphere and in the marine boundary layer.

To conduct the model calculation for a given point in the merged time series we require that data be available for all variables in Table 3. Because of lack of temporal overlap in some of the measurements (notably NOx hydrocarbons, acetone), model calculations can be done for only a small fraction of the data points (Table 2). To increase the number of points, we use in certain calculations a "fixed-hydrocarbon" version of the model in which we assume 630 parts per trillion by volume (pptv) C6H6 and 650 pptv acetone (mean values in TRACE A) and neglect the other nonmethane hydrocarbons. By relaxing the constraint on the availability of hydrocarbon and acetone data, the number of model points is greatly increased (Table 2). The errors incurred
by the fixed hydrocarbon approximation will be discussed in the context of each application. Data for HNO₃ and PAN are critical only for the NO₃ mass balance analysis presented in section 6. For all other applications, when data for HNO₃ are missing a low value is assumed; and when data for PAN are missing the PAN concentration is assumed from chemical steady state. We verified that these assumptions have a negligible effect on HO₂ levels and other relevant model results.

3. Peroxides

Figure 2 compares simulated and observed concentrations of H₂O₂ and CH₃OOH for individual points in the merged time series matched to the peroxide sampling times. Model values were sampled from the diel steady state cycle at the time of day of observation. Two outliers representing fresh fire plumes were excluded from the plots and from the statistics. Also shown on each plot are the least squares correlation coefficient \( r^2 \), the slope of the regression line \( S \), and the median ratio \( R \) of simulated-to-observed concentrations. \( S \) and \( R \) offer different measures of model bias.

We find that the model captures 78% of the observed variance of H₂O₂ concentrations. This variance is determined strongly by water vapor \( (r^2 = 0.51) \) between observed H₂O₂ and H₂O mixing ratios. Median simulated-to-observed concentration ratios are 0.99 at 0-4 km, 0.87 at 4-8 km, and 0.57 at 8-12 km. Although H₂O₂ deposition is not included in the model, its effect should be largely limited to the mixed layer and to convective outflows because the lifetime of H₂O₂ against photochemical loss is relatively short (1.5 days below 2 km). The underestimate of H₂O₂ in the upper troposphere could reflect a missing HO₂ source in the model but is also within the low-temperature uncertainties of the rate constants in the mechanism.

For CH₃OOH we find that the model captures 74% of the observed variance but is generally too low, particularly above 8 km. Median simulated-to-observed ratios are 0.59 at 0-4 km, 0.79 at 4-8 km, and 0.28 at 8-12 km. The underestimate is not outside the range of uncertainty of rate constants in the mechanism [Thompson and Stewart, 1991]. The estimated uncertainty on the rate constant for the reaction CH₃OOH + HO₂, which is the only CH₃OOH source in the model, is a factor of 2 at 298 K and a factor of 3 at 230 K [DeMore et al., 1994]. Although the underestimate of CH₃OOH could suggest the presence of major hydrocarbon precursors missing from the model, we find no parallel underestimate of CH₂O that would support this hypothesis (see section 4).

The successful simulation of the peroxides below 8-km altitude lends confidence in the O₃ production and loss rates computed by the model. At 8 to 12-km altitude the - 40% underestimate of H₂O₂ could imply an - 20% underestimate of HO₂. Considering that HO₂ accounts for ~90% of total peroxy radicals in that altitude range (Table 1b), we may expect the O₃ production and loss rates above 8 km to be underestimated by about 20%.

Singh et al. [1995] pointed out the importance of acetone photolysis (included in our model) as a primary source of HO₂ in the upper troposphere. We conducted a sensitivity calculation without acetone for the point representative of median conditions at 8-12 km (Table 1a). The H₂O₂, CH₃OOH, HO₂, and OH concentrations computed for that point decreased by 27%, 36%, 14%, and 16%, respectively, relative to the simulation including acetone. Neglecting acetone as a source of HO₂ makes the model underestimate of peroxy concentrations in the upper troposphere significantly worse.

4. Formaldehyde

Figure 3 compares simulated and observed CH₃O concentrations for individual points in the merged time series matched to the CH₃O sampling times. Again, model values were sampled from the diel steady state cycle at the time of day of observation.

---

**Figure 2.** Simulated versus observed H₂O₂ and CH₃OOH concentrations in TRACE A. Also shown are the 1:1 line, the least squares correlation coefficient \( r^2 \), the slope of the regression line \( S \), and the median ratio of simulated to observed concentrations \( R \). Observed CH₃OOH concentrations were below the detection limit of 15 pptv for 15% of the points.

**Figure 3.** Simulated versus observed CH₃O concentrations in TRACE A. Also shown are the 1:1 line, the least squares correlation coefficient \( r^2 \), the slope of the regression line \( S \), and the median ratio of simulated to observed concentrations \( R \). Observed concentrations were below the detection limit of 30-50 pptv for 56% of the points.
The model captures 62% of the observed variance. Model values tend to be too high in the lower troposphere (0.4 km) and too low in the middle troposphere (4-8 km). Most observations above 8 km are below the detection limit of 40 ppbv.

Our ability to interpret model results for CH$_2$O is evidently hampered by the small number of model points. To address this problem, we turned to the fixed-hydrocarbon version of the model which provides 926 model points for comparison with observations. The fixed-hydrocarbon approximation gives only a lower limit for CH$_2$O, because it does not allow for the possibility of high hydrocarbon concentrations, but it still allows investigation of model overestimates. We find that the worst overestimate is in the marine boundary layer over the tropical South Atlantic (mean observed conditions 26 parts per billion by volume (ppbv) O$_3$, 66 ppbv CO, 3 ppm NO, 0.015 vol/vol H$_2$O), where the mean observed concentration of CH$_2$O is 0.11 ppbv (range <0.04-0.25 ppbv) while the corresponding model mean is 0.41 ppbv (range 0.28-0.55 ppbv). The mean observed H$_2$O$_2$ and CH$_3$OOH concentrations in that region are 2.3 ppbv and 1.1 ppbv, respectively, while the corresponding model means are 3.1 ppbv and 1.7 ppbv.

The model shows some overestimate for the peroxides, which in the case of H$_2$O$_2$ could be due to deposition [Heikes et al., 1995] for this issue], but these discrepancies are small compared to CH$_2$O. We repeated the model calculation for the marine boundary layer points using observed concentrations of H$_2$O$_2$ and CH$_3$OOH as constraints, and assuming a deposition rate constant of 4x10$^{-6}$ s$^{-1}$ for CH$_2$O as a representative of a deposition velocity of 0.4 cm s$^{-1}$ over the ocean [Thompson and Zafiriou, 1983]. The mean CH$_2$O concentration in this calculation was 0.29 ppbv (range 0.21-0.48 ppbv), still 3 times higher than observed. The root of the discrepancy must therefore lie in the simulation of CH$_2$O chemistry.

Our model results for CH$_2$O can be viewed as typical of the current generation of photochemical models. We participated recently in an intercomparison of 20 models organized by the Intergovernmental Panel on Climate Change [Prather et al., 1995]. In a test simulation representative of the remote marine boundary layer we obtained a CH$_2$O concentration of 0.21 ppbv, while our models obtained values ranging from 0.13 to 0.33 ppbv. The models at the low range had unusually high CH$_2$O photolysis frequencies.

We compared the marine boundary layer measurements of CH$_2$O in TRACE A to prior shipboard measurements made over the tropical Atlantic in the same season. Lowe and Schmidt [1983] measured a mean concentration of 0.20 ppbv (range 0.10-0.34 ppbv) at 30°N-30°S latitude with no significant latitudinal dependence. These values are higher than observed in TRACE A but still lower than in our model. Harris et al. [1992] used tunable diode laser spectroscopy to measure CH$_2$O concentrations in the northern tropics during the Polarstern cruise and found a mean concentration of 0.37 ppbv at 10°N (they made no measurements further south). During the same cruise, Curtier et al. [1991] reported mean CH$_2$O concentrations of 0.4 ppbv and 0.3 ppbv over the north and south tropical Atlantic, respectively.

We evaluated our model against the Harris et al. [1992] data by taking as constraints the mean Polarstern observations at 15°N: 30 ppbv O$_3$, 90 ppbv CO, 1.3 ppbv H$_2$O$_2$, 15 ppbv NO, 0.017 mol/mol H$_2$O, temperature of 293 K, and actinometer values of J$_{NO}$ and J$_{OD}$. [Platt et al., 1992; Jacob and Klockow, 1992; Brouwers and Hofzumahaus, 1992; Hofzumahaus et al., 1992]. We obtained a model CH$_2$O concentration of 0.42 ppbv, in good agreement with the observations.

Other published measurements of CH$_2$O concentrations in clean tropical marine boundary layers include 0.4-1.1 ppbv over the Pacific [Zafiriou et al., 1980; Arlander et al., 1990] and 0.05-0.4 ppbv over the Indian Ocean [Arlander et al., 1990]. It is not clear why there is such variability in the observations and why models are unable to reproduce the lower range of values. One possibility might be the complexation of CH$_2$O with organics in the marine aerosol. To our knowledge, the only concurrent gas phase and aerosol measurements of CH$_2$O in marine air are those of Kippel and Warneck [1980]. These authors found evidence that CH$_2$O in the aerosol is predominantly present as CH$_3$OOH complexes, but they also found that the aerosol contributes only a small fraction of total atmospheric CH$_2$O.

In summary, our results point to a major gap in current understanding of CH$_2$O concentrations in the marine boundary layer. Either some of the CH$_2$O measurements are flawed or a large CH$_2$O sink is missing from the models under some conditions. Liu et al. [1992] previously noted that CH$_2$O concentrations measured in free troposphere air at Mauna Loa, Hawaii (3.4-km altitude) were a factor of 3 lower than calculated from a standard photochemical model and attributed the discrepancy to a model overestimate of OH. However, later measurements by Zhou et al. [1996] at Mauna Loa indicated that the discrepancy is driven by a model overestimate of CH$_3$OOH and that CH$_2$O concentrations calculated in a model constrained with observed CH$_3$OOH are in good agreement with observations. A global three-dimensional photochemical model study by Brasseur et al. [1996] shows, in fact, good simulation of both CH$_3$OOH and CH$_2$O at Mauna Loa. We cannot draw a parallel between Mauna Loa and the marine boundary layer in TRACE A, because the discrepancy between model and observations for CH$_3$OOH in TRACE A is far greater than for CH$_3$OOH; also, as discussed above, there is no evidence in TRACE A for a model overestimate of CH$_2$O in the free troposphere. We searched the TRACE A data set for conditions that would approximate the Mauna Loa environment described by Liu et al. [1992] and Zhou et al. [1996], but all TRACE A measurements at that altitude had much lower temperatures and humidities than at Mauna Loa (temperature and humidity are important variables controlling CH$_3$OOH concentrations in the model).

5. Ozone

Plates 1a and 1b show the horizontal distributions of the 24-hour average gross production rate of odd oxygen, P$_{O_3}$, and the net production rate, (P-L)$_{O_3}$, at different altitudes in TRACE A. The rates were computed for the merged time series matched to the NO sampling time, using the fixed-hydrocarbon approximation in order to maximize the number of model points. The errors on P$_{O_3}$ and (P-L)$_{O_3}$ caused by the fixed-hydrocarbon approximation are small; for those points where the full model (including hydrocarbons) can be applied, the median ratio of (P-L)$_{O_3}$ in the full versus fixed-hydrocarbon versions of the model is 1.02±0.01 (10) when P$_{O_3}$ is less than 20 ppbv day$^{-1}$. This regime represents 92% of all observations in TRACE A and all observations outside the continental boundary layer. Plate 1b indicates a broad region of net photochemical loss exceeding 4 ppbv day$^{-1}$ at 1.5 to 4-km altitude off the southwestern coast of Africa. This rapid loss is made possible by the albedo of persistent marine stratus decks. Gross photochemical production in the region is also high.

We see from Plate 1 that the gross production of O$_3$ decreases on average with altitude while the net production increases with altitude. Median vertical profiles of P$_{O_3}$ and (P-L)$_{O_3}$ for the southern hemisphere TRACE A data are plotted in Figure 4, and a summary O$_3$ budget for the 0 to 12-km column is given in Table 4. Both production and loss decrease with altitude, due to decreasing humidity, but production decreases slower than loss above 6 km because of high concentrations of NO. Above 6 km, photochemistry switches from a net sink to a net source of O$_3$. Similar transitions have been reported in previous model studies of the remote troposphere [Liu et al., 1980; Thompson and Cicerone, 1982; Davis et al., 1996]. Figure 4 indicates net production of O$_3$, taking place below 2-km altitude, but this portion of the budget is highly uncertain because of the large variability of O$_3$ production rates for individual points; there is a sharp contrast between the
of 10x10^10 cm^-2 s^-1 to the Amazon forest in the wet season; scaling this flux to the ratio of dry and wet season O_3 concentrations over the forest [Browell et al., 1990] would imply a dry season deposition flux to the Amazon forest of 17x10^10 cm^-2 s^-1. Another term in the O_3 budget is the time tendency, but this term is also small. Seasonal trends in the tropospheric O_3 column at sites in the South Atlantic basin are of the order of 5 DU per month, or 5x10^10 molecules cm^-2 s^-1 [Olson et al., this issue].

The close balance between chemical production and chemical loss of O_3 in the 0 to 12-km column implies that the total column amount of O_3 can be explained by in situ photochemistry, with net production above 6-km altitude balancing weak net loss below. To demonstrate this point, we conducted a one-dimensional photochemical steady state model calculation for O_3 in the 0 to 12-km column, fixing as input the median vertical profiles of O_3 precursors and other conditions from Table 1a and adopting a zero-flux upper boundary condition at 12-km altitude. The calculation assumed an O_3 deposition velocity of 0.05 cm s^-1, a uniform vertical eddy diffusion coefficient K_v = 3x10^5 cm^2 s^-1, and 24-hour average clear-sky photolysis rates. Results in Figure 5 show that it is possible to explain the O_3 concentrations and vertical gradients observed in the 0 to 12-km column in TRACE A without invoking any exogenous O_3 source.

The median lifetime of O_3 against chemical loss over the South Atlantic basin is 6 days at 0-4 km, 25 days at 4-8 km, and 0-4 km 0-8-12 km, where biomass burning influence can result in rapid O_3 production, and the marine boundary layer, where NO_x levels are low and O_3 production is slow (Plate 1). The point modeling approach is also most prone to errors in the continental boundary layer, as discussed in section 2.

We take the values in Figure 4 as our best estimates of the regionally averaged rates of O_3 production and loss over the South Atlantic basin. The corresponding integrals of 0_3 and L_0, for the 0 to 12-km column are both 1.1x10^12 cm^-2 s^-1. These values are two orders of magnitude larger than the mean stratospheric influx of O_3 in the southern hemisphere troposphere estimated to be 1-3x10^10 cm^-2 s^-1 [Gidel and Shapiro, 1980; Levy et al., 1985]. Even allowing for a slightly higher cross-tropopause flux in spring [Holton, 1990] and for preferential subsidence of air over the south tropical Atlantic [Krishnamurti et al., 1993; Loring et al., this issue], it is clear that stratospheric influx is a negligible contributor to tropospheric O_3 in the region. In situ photochemistry dominates even in the upper troposphere; the 4-km integral of 0_3 at 8 to 12-km altitude is 1.1x10^10 cm^-2 s^-1.

Deposition has only a small effect on the O_3 budget in the 0 to 12-km column. Heikes et al. [this issue] estimated a deposition flux to the Atlantic Ocean of 1.7x10^10 cm^-2 s^-1 during TRACE A. Fan et al. [1990] measured a 24-hour average O_3 deposition flux of 1.1x10^10 cm^-2 s^-1 to the Amazon forest in the wet season; scaling this flux to the ratio of dry and wet season O_3 concentrations over the forest [Browell et al., 1990] would imply a dry season deposition flux to the Amazon forest of 17x10^10 cm^-2 s^-1. Another term in the O_3 budget is the time tendency, but this term is also small. Seasonal trends in the tropospheric O_3 column at sites in the South Atlantic basin are of the order of 5 DU per month, or 5x10^10 molecules cm^-2 s^-1 [Olson et al., this issue].

The close balance between chemical production and chemical loss of O_3 in the 0 to 12-km column implies that the total column amount of O_3 can be explained by in situ photochemistry, with net production above 6-km altitude balancing weak net loss below. To demonstrate this point, we conducted a one-dimensional photochemical steady state model calculation for O_3 in the 0 to 12-km column, fixing as input the median vertical profiles of O_3 precursors and other conditions from Table 1a and adopting a zero-flux upper boundary condition at 12-km altitude. The calculation assumed an O_3 deposition velocity of 0.05 cm s^-1, a uniform vertical eddy diffusion coefficient K_v = 3x10^5 cm^2 s^-1, and 24-hour average clear-sky photolysis rates. Results in Figure 5 show that it is possible to explain the O_3 concentrations and vertical gradients observed in the 0 to 12-km column in TRACE A without invoking any exogenous O_3 source.

The median lifetime of O_3 against chemical loss over the South Atlantic basin is 6 days at 0-4 km, 25 days at 4-8 km, and 0-4 km 0-8-12 km, where biomass burning influence can result in rapid O_3 production, and the marine boundary layer, where NO_x levels are low and O_3 production is slow (Plate 1). The point modeling approach is also most prone to errors in the continental boundary layer, as discussed in section 2.

We take the values in Figure 4 as our best estimates of the regionally averaged rates of O_3 production and loss over the South Atlantic basin. The corresponding integrals of 0_3 and L_0, for the 0 to 12-km column are both 1.1x10^12 cm^-2 s^-1. These values are two orders of magnitude larger than the mean stratospheric influx of O_3 in the southern hemisphere troposphere estimated to be 1-3x10^10 cm^-2 s^-1 [Gidel and Shapiro, 1980; Levy et al., 1985]. Even allowing for a slightly higher cross-tropopause flux in spring [Holton, 1990] and for preferential subsidence of air over the south tropical Atlantic [Krishnamurti et al., 1993; Loring et al., this issue], it is clear that stratospheric influx is a negligible contributor to tropospheric O_3 in the region. In situ photochemistry dominates even in the upper troposphere; the 4-km integral of 0_3 at 8 to 12-km altitude is 1.1x10^10 cm^-2 s^-1.

Deposition has only a small effect on the O_3 budget in the 0 to 12-km column. Heikes et al. [this issue] estimated a deposition flux to the Atlantic Ocean of 1.7x10^10 cm^-2 s^-1 during TRACE A. Fan et al. [1990] measured a 24-hour average O_3 deposition flux of 10x10^10 cm^-2 s^-1 to the Amazon forest in the wet season; scaling this flux to the ratio of dry and wet season O_3 concentrations over the forest [Browell et al., 1990] would imply a dry season deposition flux to the Amazon forest of 17x10^10 cm^-2 s^-1. Another term in the O_3 budget is the time tendency, but this term is also small. Seasonal trends in the tropospheric O_3 column at sites in the South Atlantic basin are of the order of 5 DU per month, or 5x10^10 molecules cm^-2 s^-1 [Olson et al., this issue].
105 days at 8-12 km (Table 4). As the altitude increases, the loss of O₃ becomes increasingly controlled by subsidence. Subsidence from the upper to the lower troposphere over the South Atlantic takes place on a timescale of the order of 10 days [Krishnamurti et al., this issue]; we thus expect a characteristic time of about 2 weeks for O₃ to adjust to chemical steady state in the 0 to 12-km column. Such a characteristic time is sufficiently long that horizontal mass exchange with other regions could represent an important term in the budget of tropospheric O₃ over the South Atlantic basin. However, it appears from our close regional balance between chemical production and loss that this term does not provide either a major net source or a major net sink of O₃ in the South Atlantic basin troposphere, i.e., that the horizontal flux divergence is small. A general representation of the O₃ budget in the tropical troposphere consistent with this view is presented in section 7.

Tropospheric O₃ columns observed over the South Atlantic basin during the wet season are about 40% lower than observed in TRACE A [Kirchhoff et al., 1991; Olson et al., this issue; Thompson et al., this issue]. We examined whether these wet season columns could be sustained by in situ photochemical production in the same way as in TRACE A. For this purpose we decreased the NO and CO levels in the one-dimensional model to represent an atmosphere unaffected by biomass burning. Singh et al. [1990] reported a median NO concentration of 8 pptv at 0 to 6-km altitude over the Amazon basin in April-May (wet season), with little vertical gradient. Drummond et al. [1988] reported a median NO concentration of 60 pptv at 11.5-km altitude between Rio de Janeiro and Dakar in June, at the beginning of the dry season when biomass burning influence is small and tropospheric O₃ columns still assume wet season values [Kirchhoff et al., 1991]. We took these observations, which are about 3 times lower than in TRACE A, as constraints in the model. We further adopted a background CO concentration of 50 ppbv. Hydrocarbon concentrations were not modified from their values in Table 1a because they have little effect on O₃ production. As shown in Figure 5.

Median 24-hour average rates and characteristic times computed in the model for the southern hemisphere TRACE A data. O₃ is odd oxygen (O₃ = O₃ + O + NO₂ + HNO₃ + (2x)NO₃ + (3x)NO₂O₃ + peroxyacylnitrates). Column rates refer to the 4-km altitude bands. Because values are medians instead of means, (P-L)(0₃) and P(0₃) - L(0₃) are not identical.
Figure 5. Steady state O_3 concentrations computed in a one-dimensional photochemical model constrained with the median TRACE A observations for O_3 precursors (solid line) and with NO and CO concentrations reduced to reflect a background atmosphere free of biomass burning influence (dotted line). The model uses a zero-flux boundary condition at 12-km altitude. The "T" symbols are the median O_3 concentrations in the southern hemisphere TRACE A data. The "W" symbols are the mean wet season (March-May) O_3 concentrations observed at Natal, Brazil [Kirchhoff et al., 1991].

The vertical O_3 profile computed in the one-dimensional model is consistent with the mean wet season ozonesonde observations by Kirchhoff et al. [1991] at Natal, Brazil. It thus appears that the tropospheric O_3 column over the South Atlantic basin during the wet season can be sustained fully by in situ production, similarly to the dry season. Although NO_3 levels are lower than in the dry season, the O_3 levels to be sustained are also lower.

The above analysis implies a strong sensitivity of tropospheric O_3 over the South Atlantic basin to the supply of NO_3.

We show in Figure 6 the dependence of the net O_3 production rate on NO_3 concentrations in the model for points representing the median conditions observed in TRACE A at 0 to 4 km, 4 to 8 km, and 8 to 12-km altitude (Table 1a). Even at the relatively high NO_3 concentrations observed in TRACE A, O_3 production is still NO_3 limited throughout the 0 to 12 km column. A number of authors have noted that NO_3 levels in the remote troposphere are near the turnover point for net O_3 production versus net loss [Chameides et al., 1987, 1990; Jacob et al., 1992; Liu et al., 1992; Mauzerall et al., 1996; Carroll and Thompson, 1995], and this is also found in the TRACE A data below 8 km (Figure 6).

Based on the discussion above, we explain this general result as reflecting the tendency of O_3 to approach a chemical steady state determined by the NO_3 concentration.

6. Nitrogen Oxides

Several authors have examined the primary sources of NO_3 over the South Atlantic basin in TRACE A by correlating the observed NO concentrations with chemical variables and with back-trajectories [Smyth et al., this issue; Singh et al., this issue; Talbot et al., this issue; Pickering et al., this issue]. They conclude that biomass burning was a major source of NO_3 throughout the tropospheric column, and that lightning was also a major and perhaps dominant source in the upper troposphere.

Soil emissions would provide an additional source of NO_3 in the continental boundary layer [Jacob and Wofsy, 1988, 1990] but the TRACE A data are not well suited for assessing the importance of this source. Transport from the stratosphere was a negligible contributor to the NO_3 budget even in the upper troposphere [Smyth et al., this issue].

Chemical cycling between NO_3 and its oxidation products played probably a major role in maintaining high NO_3 concentrations over the South Atlantic during TRACE-A. The mean lifetime of NO_3 against reactions (8)-(10) computed in the model for the TRACE A conditions is only 4 hours at 0-4 km and 2.4 days at 8-12 km. Plate 2 shows the distribution of NO_3 concentrations over the South Atlantic basin as a function of longitude and altitude (NO is measured and NO_3 is from the photochemical model). Concentrations are high in the continental boundary layer and the upper troposphere, consistent with primary sources...
Plate 2. Mean concentration of NO\textsubscript{x} in TRACE A at 0°-30°S latitude, as a function of longitude and altitude.

from combustion, soils, and lightning; during deep convective events over the continents, NO\textsubscript{x} from combustion and soils is injected to the upper troposphere, and additional NO\textsubscript{x} is produced by lightning. However, above 4 km we find no significant decrease of NO\textsubscript{x} from continents to oceans, even though the primary sources of NO\textsubscript{x} are continental (there is little lightning over the oceans) and the lifetime of NO\textsubscript{x} is short. It appears that the high concentrations over the oceans must be maintained by chemical recycling.

We used our photochemical model to diagnose the degree to which NO\textsubscript{x} levels in TRACE A could be maintained by chemical recycling based on current understanding of tropospheric chemistry. For this purpose we computed the chemical production and loss rates of NO\textsubscript{x} at individual points in the merged time series matched to the HNO\textsubscript{3} sampling times, using the model constrained with measurements of NO\textsubscript{y}, HNO\textsubscript{3}, and PAN (details of the approach are given in section 2). Figure 7 shows the ratio of chemical loss to chemical production of NO\textsubscript{x} for individual points as a function of altitude, and Table 5 summarizes the contributions of individual reactions to the NO\textsubscript{x} budget at different altitudes. Below 4 km there is considerable scatter for individual points, reflecting primarily the relative abundances of NO\textsubscript{x} and PAN; on average, we find a balance between the source of NO\textsubscript{x} from decomposition of PAN and the sinks of NO\textsubscript{x} from oxidation to HNO\textsubscript{3} and PAN. The data below 4 km are not inconsistent with a scenario where PAN produced in biomass burning plumes decomposes to sustain NO\textsubscript{x} levels in the lower troposphere on the regional scale, but the paucity of points precludes any reliable analysis.

Above 8 km we find a systematic imbalance in the chemical
Figure 7. Ratio of 24-hour average chemical loss to chemical production rates of NO\(_x\) as a function of altitude for individual measurement time intervals in the southern hemisphere TRACE A data.

The above analysis suggests that HNO\(_3\) in the upper troposphere must be consumed on a timescale of 1 day to eventually regenerate NO\(_x\). Chatfield (1994) proposed that rapid reaction of HNO\(_3\) with CH\(_3\)O in acid aerosols might take place and yield NO\(_x\) and formic acid as immediate products. We find, however, no correlation between HNO\(_3\) and NO\(_x\) concentrations in the TRACE A data above 8 km (Figure 8), which argues against direct conversion of HNO\(_3\) to NO\(_x\) on a short time scale. Fan et al. (1994) proposed that the reaction of HNO\(_3\) with CH\(_3\)O in acid aerosols may not produce NO\(_x\) but hydroxymethylnitrate H\(_2\)C(OH)ONO\(_2\); this species could then photolyze to yield NO\(_x\) on a timescale of one week, based on laboratory data for other organic nitrates [Barnes et al., 1993]. The Fan et al. (1994) mechanism would be more consistent with the lack of correlation between NO and HNO\(_3\) in the TRACE A data.

7. Schematic for Ozone in the Tropical Troposphere

Our analysis of the TRACE A data suggests a simple schematic for the regional budget of tropospheric O\(_3\) over the South Atlantic basin. Continental NO\(_x\) emissions from South America and southern Africa are pumped to the middle and upper troposphere by convection, leading to ubiquitous net production of O\(_3\) in the upper troposphere. Eventually, the air subsides over the Atlantic Ocean and net loss of O\(_3\) takes place. Low-level advection to the continents closes the O\(_3\) cycle. We propose that this schematic can be extended to other tropical regions and provides a general explanation for the origin of O\(_3\) in the tropical troposphere, as illustrated in Figure 9. In this figure, the large-scale circulation of the tropical atmosphere is represented by the

Median 24-hour average rates and lifetimes computed in the model for the southern hemisphere TRACE A data. Because the values shown are medians, the sum of the individual rates does not add up to the total production or loss of NO\(_x\), and the median lifetime does not match exactly the corresponding concentration and loss rate; this effect is particularly noticeable at 0-4 km where the scatter of rates for individual points is large and the number of points is small. The rates of production and loss of PAN have been corrected for internal cycling within the (CH\(_3\)CO + PAN) family as described in Appendix B.

\(^{a}\) Formation of all organic nitrates other than PAN. These organic nitrates are assumed inert in the model.
Our representation of the budget of O₃ in the tropical troposphere goes back to the earliest papers arguing that the tropospheric O₃ budget is dominated by in situ production and that transport from the stratosphere is small in comparison [Chameides and Walker, 1973; Crutzen, 1973; Fishman et al., 1979; Liu et al., 1980]. Much uncertainty was attached to these early studies because of the lack of reliable NO data. Liu et al. [1980] first proposed the idea of a photochemical steady state of O₃ in the tropospheric column with net production in the upper troposphere compensating for net loss in the lower troposphere. They argued that the NOₓ in the upper troposphere driving the in situ production would originate from the stratosphere, but the TRACE A data as well as previous work [Kasibhatla et al., 1991; Penner et al., 1991; Murphy et al., 1993] show that stratospheric influx is negligible compared to combustion and lightning as a source of NOₓ in the tropical upper troposphere.

8. Conclusions

Photochemical modeling of TRACE A aircraft observations over the South Atlantic basin up to 12-km altitude indicates a close balance between chemical production and loss of O₃ in the 0 to 12-km column, with net production in the upper troposphere balancing weak net loss in the lower troposphere. Influx from the stratosphere is unimportant as a source of tropospheric O₃ in the region. We conclude that the tropospheric O₃ column can be maintained solely by in situ photochemistry. The photochemical production of O₃ is limited by the supply of NOₓ, even in the upper troposphere. Past observations of the remote troposphere indicate that NOₓ concentrations are generally near the turnover point for net O₃ production versus net O₃ loss; we interpret this observation as reflecting the tendency of O₃ concentrations to adjust to a chemical steady state defined by the available NOₓ.

Biomass burning and lightning were the two primary sources of NOₓ over the South Atlantic basin in TRACE A. Considering the short lifetime of NOₓ against oxidation (only 2-3 days at 8-12 km altitude), it appears that the high NOₓ levels observed throughout the South Atlantic basin were maintained by chemical recycling of NOₓ from its oxidation products. The low HNO₃/NO concentration ratios observed above 8 km imply rapid conversion of HNO₃ to NOₓ by a mechanism not considered in current models.

We presented a simple schematic for the origin of O₃ in the South Atlantic basin troposphere linking the large-scale Walker circulation to in situ photochemistry. Convection over South America and southern Africa injects NOₓ from combustion, soils, and lightning to the middle and upper troposphere, leading to net...
O₃ production; eventually, the air subsides over the Atlantic Ocean and net loss of O₃ takes place in the lower troposphere due to reduced NOx levels and high humidities. Low-level advection of marine air to the continents closes the O₃ cycle. We proposed that the same schematic applies to other tropical regions and offers a general representation of the O₃ budget in the tropical troposphere. This mechanism would imply a great sensitivity of the global oxidizing power of the atmosphere to NOx emissions from tropical continents.

Peroxide concentrations measured aboard the aircraft in TRACE A offered a sensitive test of the O₃ production and loss rates computed in our photochemical model. We found that the model captures 78% and 74% of the observed variances of H₂O₂ and CH₂OH concentrations, respectively. Below 8-km altitude there is no mean bias for H₂O₂ and a 30% negative bias for CH₂OH. Above 8-km the model overestimates H₂O₂ by a factor of 1.8 and CH₂OH by a factor of 3.6. Even allowing for these discrepancies, the agreement between modeled and observed peroxide concentrations is sufficiently good to lend confidence in our conclusions regarding the O₃ budget in the tropospheric column.

Formaldehyde concentrations measured aboard the aircraft provided another test of photochemistry in the model. The model captures 62% of the variance of measured CH₂O concentrations but tends to overestimate concentrations in the lower troposphere (0-4 km) and underestimate concentrations in the middle troposphere (4-8 km). The largest discrepancy between model and observations is in the marine boundary layer, where the model is too high by a factor of 3. A review of previous data in the tropical marine boundary layer indicates considerable variability in measured CH₂O concentrations that cannot be explained with current models. The issue requires further investigation.

Appendix A: Photochemical Model

Our photochemical mechanism includes inorganic and methane chemistry from DeMore et al. [1994], and non-methane hydrocarbon chemistry from Atkinson et al. [1993] and Atkinson [1994]. The rate constant and branching ratio for the CH₃OOH+OH reaction are from Vaghjiani and Ravishankara [1989]. The yield of O(¹D) from photolysis of O₃ is from Michelsen et al. [1994]. Recent data are used for the photolysis of HNO₃ [Burkholder et al., 1993], PAN [Talukdar et al., 1995], and ketones [Rober and Moortgat, 1995].

Hydrolysis of N₂O₅ to HNO₃ in aerosols is included with a rate constant determined by the collision efficiency of N₂O₅ molecules on aerosol particles [Fuchs et al., 1981, and Moortgat, 1990] and reaction probability of 0.1 based on data for aqueous surfaces [DeMore et al., 1994]. The collision efficiency is computed using the aerosol size distribution (range 0.12 to 2 μm radius) measured aboard the aircraft with 10-s resolution. The reaction probability of N₂O₅ on SAT is only 0.001-0.01 [Hanson and Ravishankara, 1993]. However, the aerosol could be in a metastable liquid state. Considering that our model uses NO as an input variable, the inclusion of N₂O₅ hydrolysis has no significant effect on the model photochemistry, but it provides a significant term in the computed mass balance for NO₃. On the other hand, the rate of hydrolysis could be underestimated if there is significant aerosol surface area outside of the 0.12 to 2-μm particle size range; on the other hand, it could be overestimated if the aerosol includes a significant population of dry particles.

Peroxide concentrations measured aboard the aircraft were measured in the lower troposphere (0-4 km) and underestimate concentrations in the middle troposphere (4-8 km). The largest discrepancy between model and observations is in the marine boundary layer, where the model is too high by a factor of 3. A review of previous data in the tropical marine boundary layer indicates considerable variability in measured CH₂O concentrations that cannot be explained with current models. The issue requires further investigation.

The issue requires further investigation.
When NO concentrations are low, formation of the organic peroxide \( \text{CH}_2(\text{OOH})\text{COOH} \) provides a temporary reservoir but does not change the ultimate fate of the carbon. With this mechanism, acetic acid has little effect on the model photochemistry even at the high concentrations measured in TRACE A.

The origin of the high acetic acid concentrations observed in TRACE A remains a puzzle. There are to our knowledge no previous observations in the upper troposphere that can be used for comparison. Figure A2 shows the relationship between acetic acid and CO in TRACE A, and compares to the relationship found in 10 dry season measurements taken at 0-4 km over the Congo rainforest during the Dynamique et Chimie en Forêt Equatoriale (DECAFE) expedition [Helas et al., 1992]. Both the TRACE A and the DECAFE data show correlations between acetic acid and CO at 0-4 km, with similar slopes, indicating acetic acid emission from biomass burning; however, the TRACE A data include, also, a major component not correlated with CO, resulting in acetic acid concentrations about 3 ppbv higher than in DECAFE for the same amount of CO. The acetic acid concentrations measured in the upper troposphere in TRACE A were not correlated with CO or any of the other variables measured aboard the aircraft except formic acid. They do, however, show a pattern of higher values over Brazil and Africa than over the South Atlantic.

Appendix B: Treatment of \( \text{NO}_x \)-PAN Interconversion in \( \text{NO}_x \) Budget Calculations

When assessing the importance of \( \text{NO}_x \)-PAN interconversion in a regional \( \text{NO}_x \) budget calculation constrained with observations for \( \text{NO}_x \) (or NO) and PAN, and with \( \text{CH}_3\text{CO}_2 \) taken to be at steady state, one must correct the rates of reactions (10), (13), and (14) to account for cycling within the chemical family \( \text{PAN} + \text{CH}_3\text{CO}_2 \rightarrow \text{PAN} + \text{NO}_x \). To illustrate the need for this correction, consider a situation where reactions (10), (13), and (14) dominate the production and loss of \( \text{CH}_3\text{CO}_2 \). Under this situation, given any specified input pair of \( \text{NO}_x \) and PAN concentrations, the steady state \( \text{CH}_3\text{CO}_2 \) concentration computed in the model yields an apparent steady state between \( \text{NO}_x \) and PAN; this steady state plays, however, no role in regulating \( \text{NO}_x \) since loss of PAN and \( \text{CH}_3\text{CO}_2 \) by reaction (10) force production of \( \text{NO}_x \) by reactions (13) and (14) to maintain the \( \text{CH}_2\text{CO}_2 \) steady state. Use of uncorrected rates \( R_{10}, R_{13}, \) and \( R_{14} \) to construct a \( \text{NO}_x \) budget can lead to the illusion of a close balance between production and loss of \( \text{NO}_x \), and to an underestimate of the chemical lifetime of \( \text{NO}_x \).

We account for this effect in our \( \text{NO}_x \) budget analyses by using corrected rates \( R' \):

\[
R'_{10} = \frac{P_{\text{PAN}}}{P_{\text{PAN}} + R_{13} + R_{14}} \quad (B1)
\]

\[
R'_{13} = \frac{L_{\text{PAN}}}{P_{\text{PAN}} + R_{13} + R_{14}} \quad (B2)
\]

\[
R'_{14} = \frac{L_{\text{PAN}}}{P_{\text{PAN}} + R_{13} + R_{14}} \quad (B3)
\]

where \( P_{\text{PAN}} \) and \( L_{\text{PAN}} \) are the chemical production and loss rates of the PAN family. In the TRACE A data set, the correction factor \( P_{\text{PAN}}/(P_{\text{PAN}} + R_{13} + R_{14}) \) ranges from 0.03 to 0.72 at 0-4 km and from 0.80 to 0.99 at 8-12 km. The correction factor \( L_{\text{PAN}}/(P_{\text{PAN}} + R_{13} + R_{14}) \) ranges from 0.23 to 0.71 at 0-4 km and from 0.76 to 0.97 at 8-12 km. The largest corrections are in the lower troposphere, where thermal decomposition of PAN often dominates the \( \text{CH}_3\text{CO}_2 \) source.
