High-Altitude Observations of the Polar Wind

High-Altitude Observations of the Polar Wind

Plasma outflows, escaping from Earth through the high-altitude polar caps into the tail of the magnetosphere, have been observed with a xenon plasma source instrument to reduce the floating potential of the POLAR spacecraft. The largest component of H⁺ flow, along the local magnetic field (30 to 60 kilometers per second), is faster than predicted by theory. The flows contain more O⁺ than predicted by theories of thermal polar wind but also have elevated ion temperatures. These plasma outflows contribute to the plasma energized in the elongated nightside tail of the magnetosphere, creating auroras, substorms, and storms. They also constitute an appreciable loss of terrestrial water dissociation into space.

Polar outflows of Earth’s ionospheric plasma, or “polar wind,” were long thought to be similar in nature (1) by analogy to the solar wind. The ionosphere has an electron density of a billion, that of the solar corona. The geomagnetic field is reshaped by the solar wind so that the outer field lines are parted from an inner region in which field lines remain reasonably dipolar. This forms high-latitude regions in which the field lines are stretched antisunward and are either connected into the interplanetary field or closed at large distances from Earth in the downstream magnetotail. Symmetric north and south vacuum wake regions are known as the magnetospheric “lobes.” These are magnetically connected to the polar cap ionospheres, subjecting them to a low-pressure boundary condition and producing a vacuum wake effect. The lobes have low plasma electron density, <1 cm⁻³ as judged from plasma wave spectral features (2).

The resultant polar wind has been studied since the late 1960s, including extensive theory and observations up to 4 Earth radii (Rₑ) (3). Direct observation of the polar wind at higher altitudes has been hampered by positive photoelectric charging of sunlit spacecraft in low-density plasmas (4). This effect excludes ions from reaching a spacecraft floating at an electric potential, relative to the plasma, that is larger than their kinetic energy per charge. It has been estimated that the outflow is adequate to supply the magnetosphere with plasma (5); however, it has been difficult to study the transport of this plasma to greater heights and determine its contribution to the region of particle acceleration and magnetospheric storm generation known to exist in the tail of the magnetosphere at tens of Rₑ (6).

The Thermal Ion Dynamics Experiment (TIDE) and Plasma Source Instrument (PSI) on the POLAR spacecraft (7) were developed for high ion flux sensitivity and to observe the spacecraft charging problem, respectively. POLAR was launched on 24 February 1996 into a 1.8 Rₑ X 8.9 Rₑ polar orbit having a period of about 18 hours. POLAR spins with a period of 6.0 s about its spin axis normal to its orbital plane. Its orbit was initially oriented near the noon-midnight meridian, with the ascending node on the dayside.

TIDE (4) measures the velocity distribution of ions once per 6-s spin of the spacecraft. It samples nearly the entire sky at a nominal resolution of 22.5° (polar) by 11.25° (spin azimuth) and in the energy range from 0.3 to 500 eV with resolution ΔE/E < 0.25. TIDE uses seven apertures, each commandable up to 1 cm² of effective area. Time-of-flight analysis of each detected particle is used to sort the ion flux by mass per charge with a resolution of m/Δm ≈ 2, which is sufficient to identify the ionospheric species H⁺, He⁺, O⁺, O²⁺, and NO⁺, as well as the He₂⁺ thought to be principally of solar origin. PSI (4) is a xenon plasma source that establishes a discharge of ~250 mA at 20 V within a xenon gas flow of 0.5 standard cm³ min⁻¹. The discharge occurs at a potential that is some-what positive of the source chassis, permitting an ion escape current up to 1 mA, which is much larger than the photocurrent demand of ~25 μA. A vernier supply biases the source relative to the spacecraft chassis in the range ±10 V, allowing fine control of the spacecraft potential relative to the plasma. The POLAR floating potential is monitored by the Electric Field Instrument (EFI) (8) on POLAR, via means of three pairs of multielement probes deployed on orthogonal wire antennas spanning up to 130 m from tip to tip. In all cases discussed here, PSI operated with a vernier bias setting that regulated the POLAR spacecraft near +1.8 V, as indicated by the EFI probes.

During the long POLAR apogee passes, the plasma density reaches low values (<1 cm⁻³), the floating potential rises to tens of volts, and often there is little or no low-energy ion plasma seen at all if PSI is off. POLAR often observes the dayside cleft, which is a localized region where energetic solar plasma is always observed, entering along field lines that connect to the dayside auroral zone. The solar wind density and particle energy are sufficient to limit spacecraft charging to a potential that is negligible relative to the solar particle characteristic energy. Thus, observations of solar plasmas are unobserved by typical positive charging levels.

Two features of the solar wind plasma entering the cleft [Fig. 1; 14:00 to 14:30 universal time (UT)] are of interest here: (i) the peaking of the H⁺ flux toward the upper end of the TIDE energy range, and (ii) the lack of spin or polar angle variation of the fluxes. The polar cap itself is typically characterized by the absence of any plasma observable by TIDE. With PSI operating, however, a narrow beam (localized in energy, spin azimuth angle, and polar angle) of H⁺ and O⁺ is observed (Fig. 1), persisting throughout this pass. The flux peaks in the middle of the plot energy range (10 to 100 eV), with a decreasing trend throughout the pass. The flux peaks in spin azimuth angle near the local magnetic field direction in each energy sweep of data (minus signs). The green color indicates peak flux near the magnetic field direction in the polar angle, whereas the variation to blue indicates a relative crosswind. Near 23:00 hours, PSI was turned off, and this caused the field aligned flows to disappear, especially for H⁺ (Fig. 1). Thus, the operation of PSI allowed us to observe low-energy plasma that could not be observed because of substantially larger spacecraft floating potentials.

The outflowing plasma velocity distribution (Fig. 2) is (i) quite cool (compared with the entering solar plasma in the cleft), that is, localized to a narrow region of the sampled velocity space; (ii) closely aligned...
with the local magnetic field; and (iii) contains O\(^+\) with bulk velocity slower than that of the H\(^+\). In the cases shown, the thermal speed measured parallel to the magnetic field is somewhat larger than the thermal speed measured perpendicular to the magnetic field, and both are smaller than the parallel flow speed.

Fig. 1. For H\(^+\) (upper panel) and O\(^+\) (lower panel), ion flux data are plotted after averaging over 20-min intervals, which are bounded by white tic marks. Within each interval, the energy flux is color-coded (10\(^{-3}\) to 10\(^{-9}\)eV\(^{-1}\) cm\(^{-2}\) sr\(^{-1}\) eV\(^{-1}\)) as indicated by the vertical brightness bar at bottom versus energy (0.4 to 450 eV, along the x or time axis), spin azimuth angle (0\(^\circ\) to 360\(^\circ\), along the y or vertical axis), and polar angle (red for 0\(^\circ\) to 67.5\(^\circ\), green for 67.5\(^\circ\) to 112.5\(^\circ\), and blue for 112.5\(^\circ\) to 157.5\(^\circ\)). No measurements exist in the polar angle range from 157.5\(^\circ\) to 180\(^\circ\). Spacecraft geocentric radius (R\(_{\oplus}\)), magnetic local time (MLT; in hours), and invariant latitude (Invl; in degrees) are indicated along the horizontal axis. The spin angles closest to the magnetic field direction and its opposite are indicated by yellow plus and minus signs, respectively, whereas the spacecraft velocity spin angle is indicated by yellow x’s. The color wheel indicates the interpretation of colors as polar angle distributions (red if peaked at small angles, green if peaked at angles near 90\(^\circ\), blue if peaked at large angles, gray if broadly distributed across the polar angle). Black radial lines in the color wheel indicate the polar angle range of the local magnetic field direction, whereas white radial lines indicate the polar angle range of spacecraft velocity. PSI was on until 23:10 hours, when it was turned off. A background measurement at 21:05 to 21:20 hours produced a data gap.

Fig. 2. H\(^+\) (A) and O\(^+\) (B) velocity (V) distributions are plotted on 19 April 1996 from 16:24:57 to 16:29:54 UT in a plane defined by the local magnetic field (x axis) and the normal vector lying in the spacecraft orbit plane (y axis). The phase space density is contoured as indicated by the saturated color bar at center. Tic marks indicate the spacecraft frame of reference (fine black), the Earth frame of reference (white), and the computed plasma frame (bold black). The velocity ranges differ between the H\(^+\) and O\(^+\) panels.

The observed polar plasma outflow is hotter and contains a higher flux of O\(^+\) than predicted by thermal outflow theory.
(7) Enhanced O⁺ content has also been noted in lower altitude observations of polar wind, and several theoretical efforts have been made to account for this, involving a variety of energetic processes, including processes that introduce energy in the electrons (3). The present observations indicate that ion heating plays a significant role. Plasma flux tubes flow through a known region of plasma heating in the dayside auroral zone (11), just before their subsequent flow antisunward across the polar cap. Nonthermal effects have only rarely and incompletely been incorporated into models of terrestrial plasma transport (12, 13), but it appears that they influence the character of the entire polar cap outflow region.

Polar plasma outflows have been cited as sources of the plasma sheet by several observers (14-17) who interpreted their data as field-aligned streams of H⁺ and O⁺ in varying mixtures, traveling at essentially the same velocity independent of mass. Typical flow parameters (17) for the H⁺ are 0.02 to 0.05 cm⁻³ and 100 to 200 km s⁻¹; that is, the fluxes have higher velocity and lower density but are similar to the fluxes reported here. Although the O⁺ is certainly of ionospheric origin, there is considerable uncertainty and interest in the ionospheric region of O⁺ origin (dayside or nightside auroral oval, or polar cap) and in the origin of the H⁺, which could be from the solar wind but arrives as a cold stream that is more characteristic of an ionospheric source.

The polar plasma outflows reported here are the same as the cold plasma streams that flow into the plasma sheet from the polar lobes, providing a supply of plasma of variable composition and energy. However, additional acceleration is required between the high-altitude polar cap and the distant plasma sheet. Near the distant lobe-plasma sheet boundary, this acceleration may have raised the H⁺ energy enough to be seen by instruments on unneutralized spacecraft.

These observations can be used to estimate the total flux of plasma ions escaping from Earth to the magnetotail through the polar caps. If we take the typical outflow speed to be 40 km s⁻¹ and the typical density to be 0.3 cm⁻³, and assume the radius of the area through which the outflow exists to be 4 Re (the region above 60° geomagnetic latitude, at 8 Re geocentric distance), the rate of outflow is ~2.5 × 10⁻⁵ H⁺ per second. At 20 km s⁻¹ and 0.05 cm⁻³, the O⁺ is much smaller in number flux but exceeds the mass flux of H⁺. If the O⁺ content is produced by auroral plasma heating processes, it may be anticipated that this will increase with geomagnetic and solar activity (18). The total outflow mass flux at low solar and geomagnetic activity is similar to known accretion fluxes of dust and meteoroids.

These observations of Earth's polar plasma fountains show that polar wind outflows continue to accelerate into the lobes of the magnetosphere, supplying the near-Earth plasma sheet of the geotail. Originating from a region of space that has previously been characterized as empty or devoid of plasma, these observations show that this region is filled with supersonic ionospheric outflows traveling along the local geomagnetic field. The observed high-altitude flows include O⁺ fluxes in excess of polar wind theory (3) but also at higher temperature. The presence of hot heavy ions in these outflows demonstrates that existing models of the polar wind require generalization to at least two dimensions so as to include the results of plasma tube circulation through regions subject to ion heating by nonthermal auroral processes.
