Investigation of the prebiotic synthesis of amino acids and RNA bases from CO2 using FeS/H2S as a reducing agent
(ferrous sulfide/pyrite/amino acids/purines/pyrimidines)

ABSTRACT An autotrophic theory of the origin of metabolism and life has been proposed in which carbon dioxide is reduced by ferrous sulfide and hydrogen sulfide by means of a reversed citric acid cycle, leading to the production of amino acids. Similar processes have been proposed for purine synthesis. Ferrous sulfide is a strong reducing agent in the presence of hydrogen sulfide and can produce hydrogen as well as reduce alkenes, alkenes, and thiols to saturated hydrocarbons and reduce ketones to thiols. However, the reduction of carbon dioxide has not been demonstrated. We show here that no amino acids, purines, or pyrimidines are produced from carbon dioxide with the ferrous sulfide and hydrogen sulfide system. Furthermore, this system does not produce amino acids from carboxylic acids by reductive amino acid reactions. Thus, the proposed autotrophic theory, using carbon dioxide, ferrous sulfide, and hydrogen sulfide, lacks the robustness needed to be a geological process and is, therefore, unlikely to have played a role in the origin of metabolism or the origin of life.

An autotrophic theory of the origin of life has been proposed (1, 2), in which carbon dioxide is reduced by ferrous sulfide and hydrogen sulfide to give amino acids, purines, pyrimidines, and a variety of other products. The proposed reactions proceed entirely on mineral surfaces, so there is no requirement for prebiotic organic compounds dissolved in the ocean. This theory has generated considerable interest as an alternative to the conventional prebiotic soup theory, but so far there has been no experimental test of whether carbon dioxide can be reduced by ferrous sulfide and hydrogen sulfide, another was commercially supplied (Aldrich, -100 mesh) pretreated by heating to 560°C in vacuo to destroy contaminating organic compounds, and a third was also commercially supplied but was not heated. After heating, the solutions were separated from the iron sulfide by centrifugation and then evaporated to dryness, dissolved in a small amount of doubly distilled water, and a portion of this solution was then treated with a mixture of o-phthalaldehyde and N-acetyI-L-cysteine before injection into a Beckman Ultrasphere C18 reverse-phase column and elution with a sodium acetate methanol gradient (15). The amino acid concentrations were estimated by excitation at 340 nm and detection at 450 nm. All surfaces coming into contact with the solutions used in this procedure were meticulously cleaned before use, glassware was heated to 560°C in air to oxidize all contaminating organic compounds, and all plasticware was rinsed three times with doubly distilled water and only used once.

Initial experiments in this study showed large yields of amino acids, and these were later shown to be a result of contamination, principally from ion-exchange resins. Meticulous attention to cleanliness and reagent purity was necessary to reduce background contamination to acceptable levels.

RESULTS

Fig. 1 shows an example of an amino acid chromatogram; trace a is the unheated sample; trace b is a sample heated for 122 days at 100°C; and trace c shows the heated sample after it was treated with 50 pmol of each of the indicated amino acids, an amount that would correspond to a yield of 5 × 10⁻⁴% for a

have been present in any nonreducing atmosphere containing
part of the proposed theory. Traces of carbon monoxide would
replace carbon dioxide, even though this is not
<10-4% purines or pyrimidines.

Therefore this system also yields
compared to solutions treated with known samples of adenine,
excitation at 340 nm and detection at 450 nm. Trace c shows the heated
sample after it was treated with 50 pmol of each of the indicated amino
acids, an amount that would correspond to a yield of 5 x 10-4% for
a four-carbon amino acid.

In addition to the long-term experiment, samples were heated for 1, 7, and 30 days with the three
types of ferrous sulfide. No amino acids were detected above
the background of the unheated sample in any of the heated
samples, which corresponds to a yield of <10-4%. This amount
is less than that detected in unheated samples of each mixture.

This result suggests that the ferrous sulfide/hydrogen sulfide/
carbon dioxide/ammonia mixture, if anything, causes decompo-
sition of the small amount of contaminating amino acids initially
present. Even if the peaks were real instead of resulting from
contamination, the yields would still be <10-4% amino acids.

It is also suggested that the proposed system can synthesize purines from ammonia and carbon dioxide (2). This claim
was investigated by using a sample that had been heated for 4 mo
with ferrous sulfide pretreated by heating to 560°C in vacuo.

Fig. 2 shows that no purines or pyrimidines were detectable in
this sample. These samples were additionally desalted by using a
Dowex 50(H+) ion-exchange column. The mixtures were
injected onto a YMC-Pack C18-AQ reverse-phase column, and
detection was made by UV absorption at 260 nm. The trace was
compared to solutions treated with known samples of adenine,
guanine, uracil, and cytosine. Therefore, the yield of purines and
pyrimidines was also <10-4%.

It could be argued that while the proposed archaic reductive
carboxylation of succinate cannot be initiated de novo using carbon
dioxide as the sole carbon source, it could have started using
organic compounds available from other prebiotic sources or
from meteorites (21, 22). To test this hypothesis we attempted
a reductive carboxylation and amination using butyrate. This
reduction would have given norvaline as a product, a com-
ponent that is relatively rare in biology and therefore has a low
background. The proposed reaction is shown:

$$\text{CH}_3\text{CH}_2\text{CH}_2\text{COO}^- + \text{CO}_2 + \text{NH}_4^+ + 2\text{FeS} + 2\text{H}_2\text{S}$$

Butyrate

$$\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{COO}^- + 2\text{H}_2\text{O} + 2\text{FeS}_2$$

Norvaline

This reaction is analogous to the reductive carboxylation of
succinate in the reverse Krebs cycle and is used by some
bacteria for the synthesis of branched-chain amino acids from
carboxylic acids (23, 24).
Heating degassed aqueous solutions of butyric acid, ammonia, carbon dioxide, hydrogen sulfide, and ferrous sulfide at 100°C for 26 days gave no detectable norvaline as a product, with a yield of <10^-4%.

**DISCUSSION**

We have demonstrated that the process proposed by Wächtershäuser of the prebiotic reduction of carbon dioxide with ferrous sulfide/hydrogen sulfide does not work under the conditions we have used, even though the Gibbs free energy is very favorable (25). For glycine synthesis we have the following reaction:

\[
2\text{CO}_2(aq) + \text{NH}_3(aq) + 3\text{FeS} + 3\text{H}_2\text{S}(g) \quad \Delta G = -36.8 \text{ kcal mol}^{-1}
\]

\[^{119}\text{O}
\text{H}_2\text{N}^- + \text{CH}_3\text{COO}^-\text{(aq)} + 2\text{H}_2\text{O}(l) + 3\text{FeS}_2\]

For adenine synthesis we have:

\[
5\text{CO}_2(aq) + 5\text{NH}_3(aq) + 5\text{FeS} + 5\text{H}_2\text{S}(g) \quad \Delta G = -35.3 \text{ kcal mol}^{-1}
\]

\[^{10}\text{H}_2\text{O} + 5\text{FeS}_2\]

\[
\text{NH}_2
\]

\[^{11}
\text{N}^- + \text{CH}_3\text{COO}^-\text{(aq)} + 2\text{H}_2\text{O}(l) + 3\text{FeS}_2
\]

There were no detectable amino acids, purines, or pyrimidines (<10^-4%), even though the Gibbs free energy change is sufficient for quantitative yields. This is another example that demonstrates the difficulty of reducing carbon dioxide at low temperatures under geological conditions. It should not be surprising that no amino acids, purines, or pyrimidines were detected, even though the free energy change is very favorable. The proposed pathway for amino acid synthesis is a reversed Krebs cycle of 5-10 steps that have large kinetic barriers in the absence of enzymes. The whole synthesis is brought to a halt if even one step retains its kinetic barrier on the ferrous sulfide surface. This attribute is in contrast to the prebiotic Strecker synthesis, in which there are no kinetic barriers except for the synthesis of hydrogen cyanide and aldehydes. These syntheses are very efficient under reducing conditions with electric discharges or ultraviolet light as energy sources. The same conclusions apply even if only the carboxylation and reductive amination of carboxylic acids is considered; this is shown below for the formation of DL-alanine.

\[
\text{CH}_3\text{COO}^-\text{(aq)} + \text{CO}_2(aq) + \text{NH}_3^-\text{(aq)} + 2\text{FeS} + 2\text{H}_2\text{S}(g) \quad \Delta G = -19.1\text{ kcal mol}^{-1}
\]

\[^{16}
\text{CH}_3\text{CH}_2\text{COO}^-\text{(aq)} + 2\text{H}_2\text{O}(l) + 2\text{FeS}_2
\]

\[^{16}
\text{NH}_3
\]

We used a number of different ferrous sulfide preparations, reaction times, and conditions, including those used to reduce thiols, double bonds, etc. (3, 4), and none of them gave products above background. It is possible that there are conditions we did not examine that would give efficient synthesis, but we consider this to be unlikely. Unless the scope of these reactions is very narrow for efficient synthesis, we would have detected substantial yields in our experiments. If a narrow set of reaction conditions are necessary, then this suggests that the proposed reactions are unlikely in most geological environments. Thus, the reduction of carbon dioxide using the ferrous sulfide/hydrogen sulfide system is not a robust process, unlike the synthesis of amino acids and other biomolecules under reducing conditions (26).

This conclusion should not discourage further investigation of the ferrous sulfide/hydrogen sulfide system as a prebiotic reagent. It may well have been important as a reducing agent for reactions of compounds produced by other prebiotic processes.
