1. Summary

We describe EUVE and ROSAT observations of the Hyades K0 III giants $\theta^1$ (vB 71=HR1411) and $\gamma$ (vB 28=HR1346) Tau. We also discuss ASCA observations of $\theta^1$ Tau. The coronal activity of these “clump” giants is intermediate between that of the Sun and of high activity stars such as RS CVn systems. There is no evidence for significant short or long term variability up to several years. Modeling of the individual and combined spectra suggest that these two X-ray and EUV-bright Hyades giants resemble in their activity levels another clump giant, $\beta$ Cet, with a peak in the emission measure distribution near $\log T \sim 6.8$, reminiscent of the Capella emission measure “bump.”

2. Introduction

The Hyades is a unique astrophysical laboratory: at a distance of only $\approx 45$ pc from the Sun, the Hyades age, mass distribution, and abundances are well known, making it a critical calibration point for all stellar evolution studies using open clusters. Equally important is the Hyades role in our understanding of stellar coronal evolution and the nature of the magnetic dynamo in stars younger than the Sun (see Stern, Schmitt, and Kahabka 1995 and references therein). Among the stars in the Hyades are the four K0 III “clump” giants, helium burning stars of $\approx 2.2 M_\odot$. The Hyades giants are perhaps the most extensively studied objects of their kind in any open cluster (e.g. Gilroy 1989). The Hyades giants and dwarfs have been extensively studied at ground-based observatories, and their photospheric abundances are well-determined (Lambert and Ries 1981, Cayrel et al. 1985, Griffin and Holweger 1989, Ruck and Smith 1993). The metallicity for the Hyades giants is log [Fe/H]=+0.15 compared to the Sun, and C and O are under-abundant by about 0.4 dex (Lambert and Ries 1981, Cayrel et al. 1985, Griffin and Holweger 1989).

The Hyades giants all exhibit chromospheric and coronal activity (see Table 1; Baliunas, Hartmann, and Dupree 1983, Stern et al. 1992, and Stern, Schmitt, and Kahabka 1995). Residing in the “clump” region of the H-R diagram, the Hyades giants are also important as they lie near the coronal “dividing line” separating stars with strong and weak (or no) X-ray emission (see Haisch et al. 1991 and references therein). At present, the only other example of such a “clump” giant observed by EUVE is the nearby star $\beta$ Cet (Ayres et al. 1998). A major unresolved question is whether the coronal temperature structure and abundance pattern displayed by this star is typical, or if there is a wide variation among the giants themselves. The evolutionary status of such field stars is not nearly as well known as for the cluster giants. Hence to understand the EUV characteristics of these giants as a group, and how they fit into the overall picture of post-main sequence coronal evolution, we need to observe stars with known ages, masses, and compositions, such as the Hyades giants. The Hyades giants also represent a critical link in our unraveling of the Capella system, the nearby binary (G0 III + G 8 III) that has been observed extensively with EUVE (Dupree et al. 1993, Brickhouse et al. 1995,
The four Hyades giants present an intriguing puzzle. Optically, they are nearly indistinguishable from each other: all are spectral type K0 III (\( \epsilon \) Tauri is occasionally given a G9.5 III classification), and have V-R colors within 0.02 mag (Baliunas, Hartmann, and Dupree 1983; Gilroy 1989). Yet two of the giants (\( \theta^1 \) and \( \gamma \) Tauri) are 20-50 times brighter in X-rays than the other two, \( \delta \) and \( \epsilon \). In this respect, the two groups of Hyades giants may have an analog in the dichotomy between the giants \( \beta \) Cet and \( \beta \) Gem, which lie quite near each other in the H-R diagram, yet \( \beta \) Cet has an X-ray luminosity \( \approx 100 \) times that of \( \beta \) Gem (see discussion in Eriksson et al. 1983). With X-ray luminosities of \( \approx 10^{30} \text{ erg s}^{-1} \), \( \theta^1 \) and \( \gamma \) Tauri are, in fact, even brighter in X-rays than the most active Hyades G-dwarf, vB 50 (Stern et al. 1992, Stern, Schmitt, and Kahabka 1995). \( \theta^1 \) Tau is known to have a wide binary companion, which is likely an early M dwarf (Griffin and Gunn 1977). However, the typical X-ray luminosity of a Hyades M dwarf is \( \approx 1\% \) of the X-ray luminosity of \( \theta^1 \) Tau: it is thus very unlikely that the binary companion contributes significantly to the system's coronal activity (Stern et al. 1992). In addition, correlation with chromospheric activity including Mg II fluxes (see Table 1) suggests strongly that the optically faint binary companion is not the source of \( \theta^1 \) Tau's coronal emission.

The coronally active Hyades giants are also well within the sensitivity range of the EUVE spectrometers: \( \theta^1 \) Tau was detected in the Al/C filter in the RAP survey at 35 c/ksec (McDonald et al. 1994): although this flux is most likely from the He II 304 Å line, it could also contain a contribution from the Fe IX-XI lines at 170-180 Å. Because the giants vary in X-ray luminosity by less than a factor of two over a decade (Stern, Schmitt, and Kahabka 1995), show no evidence of flaring or other short time-scale variability, and have rotation periods \( \sim 140 \) days (Baliunas et al. 1991), observing the Hyades giants, even at different epochs, allows us to combine EUVE and other data sets for a full picture of the star's emission measure distribution from \( 10^5 \) to \( 10^8 \) K.

2.1 Capella and the Hyades Giants

Capella is a binary system (104 d period) composed of a G8 III primary, a “clump” giant of nearly the same mass as the Hyades giants (Pilachowski and Sowell, 1992), and a rapidly rotating, G0 III secondary, believed to be a Hertzsprung gap star. Because EUVE cannot resolve the individual components of the system, using the EUV characteristics of a Hyades giant as a “stand-in” for the Capella primary should help in resolving the current controversy regarding the identification of the Capella components with features in the Capella emission measure distribution (DEM). Dupree et al. (1993) and Brickhouse et al. (1995) noted a “bump” in Capella’s DEM near \( \log T \approx 6.8 \), presumably the result of enhanced Fe XVIII-XIX line emission. Is such a “bump” the result of a composite binary temperature distribution, or something intrinsic to the nature of one or both of Capella’s giants? By examining single stars similar to the individual components of Capella (e.g. the Hyades giants for the G8 III component), we should be able to gain a
significant insight into this question. Ayres and Brown (1994), in their analysis of the EUVE spectrum of 31 Com (another likely Hertzsprung gap star), have suggested that the Capella EUVE spectrum (Dupree et al. 1993) is really composite, made up of the “flarelike” corona from the more active G0 III secondary (with lines formed at $\approx 10^7$ K, similar to 31 Com), added to the spectrum of the less active G8 III “clump” primary (with lines formed at $\approx 5\times10^6$ K). If this hypothesis is true, then other, post He-flash or “clump” giants should also exhibit a similar DEM as the Capella primary, with line emission at Fe XVIII-Fe XIX dominating the EUV SW spectra. $\beta$ Cet is one example of this class which has already been observed by EUVE (Ayres et al. 1998). However, this picture is complicated by the fact that the 31 Com EUVE spectrum appears to have its peak emission measure at a temperature higher ($\log T \approx 7.0$) than Capella's $\log T \approx 6.8$ “bump” (Dupree et al. 1995).

3. Existing X-Ray Observations of the Hyades Giants

3.1 ROSAT All-Sky Survey Data

The ROSAT All-Sky Survey (RASS) observed the four Hyades giants between 1990 July 30 and 1991 January 25: all the giants were detected, with $\theta^1$ and $\gamma$ Tau being detected at a level roughly 25-50 times that of $\delta$ and $\epsilon$ Tau (Stern, Schmitt, and Kahabka 1995). The X-ray fluxes are indicated in Table 1, assuming all the giants at $d=45$ pc (the X-ray flux differences would be at most 10% changed if we used the proper motion distances indicated in the table). Because of the short exposure time ($< 600$ s), this data is useful for flux measurements, not spectral modeling.

3.2 ROSAT Pointed Observations

Pye et al. (1995) obtained ROSAT PSPC spectra of $\theta^1$ and $\gamma$ Tau in September 1992. To adequately fit the ROSAT spectra requires at least a 2 temperature (Raymond 1993) model. The model results were, for $\theta^1$ Tau: $\log T_1 = 6.2$, $EM(52)_1=1.4$, $\log T_2 = 6.9$, $EM(52)_2=3.7$, for $\gamma$ Tau: $\log T_1 = 6.4$, $EM(52)_1=1.2$, $\log T_2 = 6.8$, $EM(52)_2=1.6$ ($EM52$ = volume emission measure in $10^{52}$ cm$^{-3}$).

3.3 ASCA Observations

$\theta^1$ Tau was observed by ASCA from 1344 UT 18 September to 0751 UT 19 September 1995 for a total exposure time of $\approx 30$ ksec. The count rate in the SIS0 detector was $\sim 0.17$ counts/sec. No ASCA observations of $\gamma$ Tau were scheduled. Unlike the very active RS CVn systems, $\theta^1$ Tau exhibits no strong X-ray variability on short or long time scales: the observed SIS count rate is nearly exactly that predicted using the ROSAT PSPC data taken 3 years earlier, and there are no obvious flares.
4. EUVE Observations and Analysis

EUVE observed \( \theta^1 \) Tau for a total of \( \approx 165 \) ksec net exposure during the period 21 January to 1 February 1996, and \( \gamma \) Tau for a net exposure of \( \approx 240 \) ksec for 7 to 11 February 1997. Spectra were extracted in the SW (70-150 \( \AA \)) and MW (140-380 \( \AA \)) bands using the IRAF euv software package (egocs1.6.2; egodata1.13), and the routine “euvextract”. The background data for each spectrum was fitted using a 3rd order polynomial function, then the extracted spectra were fitted using a sum of the (then fixed) background spectrum and a multiple gaussian line fitting package developed at LMSAL using IDL. Inputs to the multiple gaussian fitting routine were a series of known strong line locations; the number of line counts, line wavelength, and width were allowed to vary (the latter two within reasonable bounds given the resolution of the SW and MW spectra). In addition, light curves of the DS (Deep Survey) band (70-140 \( \AA \)) were made for both observations.

5. Results

5.1 EUVE

SW and MW Spectra and Line Fluxes

In Figure 1 (a) we show the results of spectral fitting for \( \theta^1 \) Tau’s SW spectrum, and in Figure 1 (b) a portion of the MW spectrum for the same object. (325-365 \( \AA \)). The full MW spectrum is not shown, since the region between 140 and 290 \( \AA \) produced only upper limits, and the region from 290-320 \( \AA \) is dominated by geocoronal He II 304 \( \AA \) radiation. In Figure 2 (a) and (b) we show the same results for \( \gamma \) Tau.

In Table 2 we give the line fluxes and upper limits for line emission from \( \theta^1 \) Tau, and in Table 3 the same information for \( \gamma \) Tau.

5.2 Short and Long Term Variability

The EUVE observations of both \( \theta^1 \) and \( \gamma \) Tau are perfectly consistent with a constant count rate over \( \sim 10 \) (\( \theta^1 \)) and 4 (\( \gamma \)) days (Figures 3 and 4). Earlier ROSAT all sky survey data demonstrated that \( \theta^1 \) Tau had increased in X-ray luminosity by no more than \( \sim 50\% \) over the course of a decade (Stern, Schmitt, and Kahabka 1995).

6. Temperature Distribution and Abundances for \( \theta^1 \) Tau

Given that there is now ASCA data on \( \gamma \) Tau, and the EUVE spectra are of relatively poor S/N quality, we concentrated our modeling efforts on \( \theta^1 \) Tau. The combined ASCA SIS, GIS and ROSAT data are not adequately fit using a single temperature, solar abundance model (MEKAL or MEKA). Adding a second component improves the fit, but only in the region below 0.5 keV, where only the PSPC is sensitive. However, unlike
the case of many active binary systems (e.g. White et al. 1994, Antunes et al. 1994, Stern et al. 1995), which require low (~1/3) Fe abundances, the ASCA fit is improved in the case of $\theta^1$ Tau by allowing the Mg abundance to increase by about a factor of 2 ($\mathrm{Mg/H} = 1.86 \pm 0.25$, 90% L.O.C. 1 parameter). However, systematic errors are likely to dominate the error budget, and the reduced $\chi^2$ is only $\sim 1.3$. Allowing the other elemental abundances to vary seems to have little effect; slight improvements in the fit are gained with a near-zero Ne abundance. The overall fit is shown in Figure 5 (SIS and GIS: top two curves in upper box, PSPC: bottom curve in upper box). Note that the contributions to $\chi^2$ are largely from the SIS data. We have also fit the spectrum to about the same level using a (corrected) Chebyshev polynomial model of the emission measure (EM) distribution (Figure 6). In this case, $\mathrm{Mg/H} \sim 1.6$, showing the systematic effect of changing the temperature distribution. Although we have used the latest released version of SISRSP to generate a customized response matrix for our observation date, allowing the gain to decrease by $\approx 2\%$ produces a significant improvement in the fit. Since the SIS data were taken less than 6 months ago, and the latest effects of resolution degradation have not been taken into account in the v0.9 response matrices, this is understandable. There may be other unresolved calibration issues, i.e. near $\approx 1$ keV.

Combining our ASCA data with ROSAT data taken 3 years previously, we find that the ROSAT 0.5-1.5 keV region is well-fit by the same model used for the ASCA SIS0 data. However, the counts below $\approx 0.5$ keV in the ROSAT PSPC require the addition of a second component at $\approx 0.12$ keV.

6.1 DEM Modeling

The EUVE SW and MW spectra for $\theta^1$ Tau clearly shows the presence of line emission from ionization stages Fe XV through XXI. With the EUVE_FIT fitting routine, which uses the sum of terms of an Nth order Chebyshev polynomial to characterize the EM distribution (Stern et al. 1995), we find a peaked DEM near $\log T \sim 6.8$. The fitted SW and MW spectra and the derived DEM are shown in Figures 7 and 8 respectively. Note that the region around 304 Å has been removed from the MW spectrum to exclude it from the spectral fit, and that the spectrum extends out to at least 360 Å demonstrating the low column ($N_H < 5 \times 10^{18}$ cm$^{-2}$) to the Hyades.

7. Summary

All four of the Hyades giants show some evidence of coronal activity, with $\theta^1$ and $\gamma$ Tau the brightest in X-rays. All observations to date (with EUVE, ASCA, and ROSAT) suggest that these giants are of intermediate activity level compared to the Sun and the very active RS CVn systems. $\theta^1$ Tau, unlike more active RS CVn systems, has a fairly narrow temperature distribution, peaked at $\log T \sim 6.8$. As with $\beta$ Cet, the Mg/H abundance is enhanced, perhaps by as much as a factor of 2. $\theta^1$ and $\gamma$ Tau exhibit little of the short term variability seen in active stars, and is relatively constant in X-ray
luminosity over several years. The Hyades giants may well be an excellent analog for the G8 III member of the Capella system, accounting for the emission measure “bump” seen in the EUVE spectrum.

8. Acknowledgements

We thank K. Ebisawa, K. Mukai, K. Arnaud, and M. Tripico for much help with the ASCA data analysis, XSPEC models, and FTOOLS Perl problems. EUVE - contract & hospitality of CEA. We also thank S. Drake for supplying a corrected version of K.P Singh’s Chebyshev polynomial DEM models for XSPEC. R.A.S. was supported in part by NASA/GSFC contract P.O. S-57777-F and by the Lockheed Martin Independent Research Program.

Figure 7
We describe EUVE and ROSAT observations of the Hyades K0 III giants $\theta^1$ (vB 71=HR1411) and $\gamma$ (vB 28=HR1346) Tau. We also discuss ASCA observations of $\theta^1$ Tau. The coronal activity of these "clump" giants is intermediate between that of the Sun and of high activity stars such as RS CVn systems. There is no evidence for significant short or long term variability up to several years. Modeling of the individual and combined spectra suggest that these two X-ray and EUV-bright Hyades giants resemble in their activity levels another clump giant, $\beta$ Cet, with a peak in the emission measure distribution near log T $\sim$ 6.8, reminiscent of the Capella emission measure "bump."
