Short title: AIRCRAFT IMPACT ON NOy
Submitted to the Journal of Geophysical Research
August 16, 1999
Abstract. The impact of aircraft emissions on reactive nitrogen in the upper troposphere (UT) and lowermost stratosphere (LS) was estimated using the NO$_x$-O$_3$ correlation obtained during the SASS Ozone and NO$_x$ Experiment (SONEX) carried out over the US continent and North Atlantic Flight Corridor (NAFC) region in October and November 1997. To evaluate the large scale impact, we made a reference NO$_x$-O$_3$ relationship in air masses, upon which aircraft emissions were considered to have little impact. For this purpose, the integrated input of NO$_x$ from aircraft into an air mass along a 10-d back trajectory ($\Delta$NO$_x$) was calculated based on the ANCAT/EC2 emission inventory. The excess NO$_x$ (dNO$_x$) was calculated from the observed NO$_x$ and the reference NO$_x$-O$_3$ relationship. As a result, a weak positive correlation was found between the dNO$_x$ and $\Delta$NO$_x$, and dNO$_x$ and NO$_x$/NO$_y$ values, while no positive correlation between the dNO$_x$ and CO values was found, suggesting that dNO$_x$ values can be used as a measure of the NO$_x$ input from aircraft emissions. The excess NO$_x$ values calculated from another NO$_y$-O$_3$ reference relationship made using in-situ CN data also agreed with these dNO$_x$ values, within the uncertainties. At the NAFC region (45°N - 60°N), the median value of dNO$_x$ in the troposphere increased with altitude above 9 km and reached 70 pptv (20 % of NO$_x$) at 11 km. The excess NO$_x$ was estimated to be about half of the dNO$_x$ values, corresponding to 30 % of the observed NO$_x$ level. Higher dNO$_x$ values were generally found in air masses where O$_3$ = 75 – 125 ppbv, suggesting a more pronounced effect around the tropopause. The median value of dNO$_y$ in the stratosphere at the NAFC region at 8.5 – 11.5 km was about 120 pptv. The higher dNO$_y$ values in the LS were probably due to the accumulated effect of aircraft emissions, given the long residence time of affected air in the LS. Similar dNO$_y$ values were also obtained in air masses sampled over the US continent.
1. Introduction

Nitrogen oxide radicals ($\text{NOx} = \text{NO} + \text{NO}_2$) play a critical role in the photochemistry of ozone ($\text{O}_3$) and hydrogen oxide radicals ($\text{HOx} = \text{OH} + \text{peroxy radicals}$) in the upper troposphere (UT) and lowermost stratosphere (LS). The major sources of total reactive nitrogen ($\text{NOy} = \text{NO} + \text{NO}_2 + \text{NO}_3 + \text{HNO}_2 + \text{HNO}_3 + \text{HNO}_4 + 2\text{N}_2\text{O}_5 + \text{PAN} + \text{other organic nitrates} + \text{aerosol nitrates}$) in the UT are transport from the stratosphere, NO production by lightning, aircraft NO$_x$ emissions, and convective transport of NO$_x$ rich air from the continental surface where NO$_x$ is produced by fossil fuel combustion and other processes. According to 3-D model calculations, the contribution from each source is similar in magnitude at northern midlatitude UT during winter, while lightning becomes a major source in summer [Lamarque et al., 1996]. Because of a rapid growth in air traffic in recent years, greater attention has been paid to the impact of aircraft NO$_x$ emissions on the O$_3$ chemistry in the UT and LS. Model calculations predict that aircraft emissions can have significant impact on large scale NO$_x$ distributions in the UT and LS in the northern midlatitudes and high latitudes [Brasseur et al., 1996]. The emissions are especially extensive in the North Atlantic Flight Corridor (NAFC) region, where commercial air traffic is heavy at altitudes between 10 and 12 km [Baughcum et al., 1996; Gardner, 1998]. The maximum increase in NO$_x$ in the NAFC region was estimated to be between 50 and 90 parts per trillion (pptv) at 200 hPa for July, based on several 3-D model calculations using a 1990 fleet of subsonic aircraft [Brasseur et al., 1996, 1998 and references therein]. Sharp increases in NO$_x$ concentrations within aircraft contrails were observed in the eastern NAFC region and an aircraft source was successfully identified in some cases [Schlager et al., 1997; Klemm et al., 1998]. Although the large-scale effect (e.g. corridor effect) from aircraft emissions is more difficult to evaluate from the observation, a regional scale enhancement in NO/NO$_y$ ratio was identified in the LS over the east coast of the US continent by comparing the observed ratios with those of trajectory model calculations [Witte et al., 1997].

The Subsonic ASSessment (SASS) Ozone and NOx experiment (SONEX) was carried out using NASA's DC-8 aircraft in October and November 1997. Most of the aircraft measurements were
made over the US continent and the NAFC region (Figure 1). Four intensive flights were made from both Bangor, Maine (45°N, 68°W) and Shannon, Ireland (53°N, 9°W). A substantial amount of the data was obtained at altitudes between 8 and 11.5 km in both the UT and LS. Details of the experiment are described by Singh et al. [1999].

In this paper, the impact of aircraft emissions on amount of reactive nitrogen was estimated using the NOy - O3 correlation. This is because a positive correlation between NOy and O3 was generally observed in the UT and LS [Murphy et al., 1993; Ridley et al., 1994; Kondo et al., 1996] and the aircraft emissions can alter their correlation [Koike et al., 1997]. In Plate 1, a correlation plot between NOy and O3 using all of the 10-s SONEX data obtained above 8.5 km are shown. In this plate, we excluded the data obtained within aircraft plumes, influenced by lightning, or affected by recent convective transport, as described in detail in the following section. As seen in this plate, the NOy values at 45°N - 60°N and those over the US continent are generally higher than those obtained over the west coast of the US and at 30°N-45°N and 60°N-70°N, where air traffic density is lower. As described in the following sections, a reference NOy - O3 relationship will be derived using data from air masses, in which aircraft emissions are considered to have little impact, i.e. "background air". The excess NOy (dNOy) will be estimated using this reference relationship. The statistical analyses of these dNOy values will be made for the data obtained at 45°N - 60°N over the Atlantic (corresponding to the NAFC) and the US continent. The excess NOx (dNOx) will also be estimated using the reference NOx/NOy ratio in the background air.
2. Measurements and Data

2.1. Measurements

The NO and NO\textsubscript{y} instrument used for SONEX was very similar to that used during NASA’s Pacific Exploratory Mission West-B (PEM-W-B) conducted in 1994 [Kondo et al., 1997]. Both NO and NO\textsubscript{y} were measured using a chemiluminescence technique. NO\textsubscript{y} compounds were catalytically converted into NO on the surface of a heated gold tube with the addition of CO. The inlet tube for air sampling faced rearward discriminating against particles of diameter larger than about 1 µm. The data were recorded every 1-s, however, 10-s averaged data were used in this study. The precision of the 10-s NO and NO\textsubscript{y} measurements at 10 km estimated from the photon counts fluctuations (2σ) was 6 and 19 pptv for the NO and NO\textsubscript{y} values of 100 and 800 pptv, respectively. The absolute accuracy was estimated to be 8 and 10 % for these NO and NO\textsubscript{y} values.

During the SONEX project the same gold tube was used for all NO\textsubscript{y} measurements. Other than operating the instrument using synthetic air, no attempt was made to clean the tube. The conversion efficiency of NO\textsubscript{2} in ambient air was 99±1 % during each flight. Possible interference in the NO\textsubscript{y} measurements from the conversion of HCN, NH\textsubscript{3}, and CH\textsubscript{3}CN was checked in the laboratory and during the flights. The conversion efficiency of HCN in dry synthetic air was between 0.5 and 4 % on the ground before, during, and after the mission. It was also measured during the two test flights (at 6.4–11.9 km), using two independent NO\textsubscript{y} channels and by adding a known amount of HCN gas into one of the channels. For one flight, the conversion efficiency was 2.1±0.5 % for the O\textsubscript{3} and H\textsubscript{2}O mixing ratios of 62–140 parts per billion (ppbv) and 23–235 parts per million (ppmv), respectively. For the other flight it was 1.6±0.5 %, although the O\textsubscript{3} and H\textsubscript{2}O values were not measured. From these results, HCN was estimated to have contributed about 4 pptv to the SONEX NO\textsubscript{y} data assuming an average HCN mixing ratio of about 200 pptv [Rinsland et al., 1982; Mahieu et al., 1995]. The conversion efficiencies of NH\textsubscript{3} and CH\textsubscript{3}CN were also measured in the laboratory at 1-3 and 0.5-2 %, respectively. Assuming mixing ratios of NH\textsubscript{3} and CH\textsubscript{3}CN in the UT of 1 pptv [Ziereis and Arnold, 1986] and 200 pptv [Hamm et al., 1989], the interference from these species is
considered to be negligible.

During the SONEX experiment, the actinic flux was measured using grating monochromators to calculate photolysis rate of NO$_2$ (J(NO$_2$)) [Shetter and Muller, 1999]. The photostationary state NO$_2$/NO ratios were calculated using the measured values of O$_3$, temperature, pressure, and J(NO$_2$) for periods when the solar zenith angles were lower than 87°. The NO$_x$ mixing ratios were calculated from these NO$_2$/NO ratios and the observed NO mixing ratios. The calculated NO$_2$/NO ratios and NO$_x$ values were compared with those calculated using a box model in which a more complete photochemistry was included [Jaegle et al., 1998]. As a result, they agreed within 30 % and 10 %, respectively, at altitudes above 7 km. Simplified chemistry was used in this study to maximize the amount of NO$_x$ data.

In this study, 10-s averaged data of O$_3$, N$_2$O, and CO were also used. The O$_3$ measurements were made using a chemiluminescence technique, and N$_2$O and CO were measured using a tunable diode laser system. The concentration of condensation nuclei (CN) with a diameter larger than 15 nm (CN fine particle; TSI model 3760) [Anderson et al., 1999] was also used in this study. The unit of CN concentration was normalized to 0°C temperature and 1013 hPa (STP-cm$^3$) to represent the CN mixing ratio. Nonmethane hydrocarbons (NMHCs) and halocarbons were measured by collecting whole air samples and analyzing them using gas chromatography and flame ionization and electron capture detectors. The detection limit and sampling frequency of these measurements are summarized by Singh et al. [1999] and Simpson et al. [1999].

2.2. Data Selection

During the SONEX experiment, most of the data were obtained at altitudes between 8 and 11.5 km. Air masses with O$_3$ values lower and higher than 100 ppbv were defined as tropospheric and stratospheric, respectively. The stratospheric air masses were sampled at potential temperatures between 310 and 360 K, within the lowermost stratosphere (LS), the region above the midlatitude tropopause and below the isentrope touching the tropical tropopause, roughly 385 K, defined by Holton et al. [1995]. Based on the Microwave Temperature Profiler (MTP) tropopause height data,
the LS data were obtained within 2 km from the tropopause. The MTP data also showed that air masses with O$_3$ values higher than 100 ppbv were sometimes obtained below the tropopause even though a clear signature of stratospheric air intrusion was not seen in the airborne Differential Absorption Lidar (DIAL) O$_3$ data. However, in general, air masses with O$_3$ values higher than 100 ppbv were considered to have the same chemical characteristics as those from the LS. Similarly, air masses in which O$_3$ values lower than 100 ppbv observed above the MTP derived tropopause height were regarded as the UT ones.

In the present study, an increase in NOx and NOy from aircraft emissions was estimated for two study areas. The first area chosen was at latitudes between 45°N and 60°N and at longitudes between 0°W and 80°W. This data set was obtained mostly during the intensive flights from Bangor and Shannon (Figure 1). Air traffic density is quite high in this area and will be referred to as the "NAFC region" in the following. The other area was located over the US continent at latitudes between 35°N and 45°N and at longitudes between 70°W and 120°W. The data set in this area was obtained during the two transit flights made on October 13, 1997 (971013) and 971112 between NASA Ames on the US west coast and Bangor on the east coast. This area will be referred to as the "US continent region".

When the measurements were made within the heavy air traffic region, sharp simultaneous increases in NO and NOy values were often seen [Sugita et al., 1999; Anderson et al., 1999]. These air masses were most likely sampled within aircraft plumes. The increase in the 1-s NO and NOy data ranged from 100 pptv to a few ppbv. The time duration of the enhancement ranged from 1-s to 60-s, with a median value of 4-s. Given the typical cruise speed of the NASA DC-8 aircraft of 200-250 m/s, the horizontal scales of the plumes were smaller than about 10 km with a typical size of about 1 km. Based on the Gaussian plume model, aircraft emission plumes are diluted to background concentrations within 5 to 10 hours for a typical wind shear condition with a corresponding horizontal size of 20 km [Schlager et al., 1997; Gerz et al., 1998]. Although the size of the NOy enhancement observed from the NASA DC-8 depends on the geometry of the plume crossing, the maximum size of the observed plume was comparable to these estimates. These estimates were also
consistent with a plume age of 10 minutes to 10 hours estimated using peak NOy mixing ratios observed during SONEX [Anderson et al., 1999]. In this study, the data obtained within the plumes were excluded in the evaluation of the large scale impact from the aircraft emissions. This was because the sampling frequency of the plumes depends on the location and time of the measurement (many plumes were observed when the measurements were made in air masses just after heavy air traffic had finished) and an inclusion of these data could be a potential cause of a bias in estimating the aircraft impact. The excluded data corresponded to 6 % of the entire data set at the 8.5 to 11.5 km altitude range. Because they were relatively small amount, the results of this study would not change significantly even the plumes were included in the analyses.

A clear signature of NO production by lightning was seen during four flights, on 971013, 971029, 971103, and 971109 [Thompson et al., 1999; Pickering et al., 1999]. In these cases the NOx and NOy mixing ratios increased more than 1 ppbv and NOx/NOy ratios ranged between 0.4 and 1.0 suggesting that NO production by lightning had occurred within a few days prior to the measurements. These results were generally consistent with the analyses of the air mass trajectories, convective activities using cloud images, and lightning activities detected by the US ground based lightning network [Thompson et al., 1999; Pickering et al., 1999]. Possible influences from the lightning were also observed on 971020 and 971028. In this study, all of the data likely to have been influenced by NO production by lightning were excluded. It should be noted, however, that the influence of lightning cannot be identified in an air mass, once the NOx in the air mass is diluted down near the background level. Consequently we could not completely remove from our analysis the data which might have been affected by NO production from lightning. The contribution from lighting will be revisited in Section 3.2.3.

The vertical profile of the CO in the troposphere is shown in Figure 2 using all of the data except for those obtained from aircraft plumes and clearly influenced by lightning. The median values and 67 % ranges in the NAFC region are also shown. As seen in this figure, the CO mixing ratio generally decreased with altitude and the median values were between 76 and 82 ppbv at 9 to 11 km. These values were systematically lower than the median CO values of 100 to 105 ppbv
obtained in the continental or maritime air masses in the UT over the middle to high latitude western Pacific in September and October [Kondo et al., 1996]. In Figure 3, a correlation plot between NOy and CO is shown using the data obtained at altitudes above 8.5 km. Different symbols are used for the UT and LS data. The NOy mixing ratio did not generally have a positive correlation with the CO mixing ratio in the UT. These results suggest that NOy values in most of air masses in the UT obtained during SONEX had not been influenced by recent convective transport of polluted continental surface air. To eliminate the possible influence from recent convection, the data with CO values higher than 100 ppbv was excluded in this study. In addition, data showing a clear positive correlation between CO and NOy, were also excluded. The excluded data by these criteria corresponded to 19% of the entire UT data set obtained above 8.5 km.

The correlations of NOy with nonmethane hydrocarbons such as ethyne (C$_2$H$_2$), ethane (C$_2$H$_6$), and propane (C$_3$H$_8$), and halocarbons such as perchloroethene (C$_2$Cl$_4$), methyl iodide (CH$_3$I), and CHBr$_3$ were also examined. No clear positive correlation was seen in the UT. In fact, NOy decreased with increasing mixing ratios of these hydrocarbons and halocarbons for NOy mixing ratios higher than 300 pptv (not shown). C$_2$H$_2$, C$_2$H$_6$, C$_3$H$_8$, and C$_2$Cl$_4$ are emitted in urban areas. CH$_3$I and CHBr$_3$ are considered to be good indicators of maritime air mass. The photochemical lifetimes of these species are comparable or shorter than that of CO. Consequently, the lack of a clear correlation of NOy with these species further confirms that the data selected in this study were generally free from the recent convective transport of air influenced by urban and other surface sources.
3. Results and Discussion

3.1. Reference NO$_y$-O$_3$ Relationship

To estimate the increase in the NO$_y$ mixing ratio due to aircraft emissions, we utilized a method that uses the NO$_y$-O$_3$ relationship. In this method, a reference NO$_y$-O$_3$ relationship was estimated using data in air masses upon which aircraft emissions were believed to have had little impact, i.e. "background air masses". To select the background air masses at 8.5-11.5 km, two independent approaches were taken. As described below, the agreement in the estimates on the excess NO$_y$ derived from these two approaches was evaluated and the first approach described below was used for the further analyses.

For the first approach, 10-d back trajectories were calculated using a kinematic method for air masses sampled every 1 minute on board the NASA DC-8. The European Center for Medium-Range Weather Forecasts (ECMWF) data were used for this calculation. Then an integrated value of expected NO$_x$ input from the aircraft emissions along each trajectory was calculated using the monthly mean values of the three dimensional NO$_x$ emission distribution for October 1992, compiled in the ANCAT/EC2 emissions inventory [Gardner, 1998]. No chemical loss or diffusion process and no diurnal variation in NO$_x$ emission rate was taken into account for this calculation, although some initial dilution effect was included because the emission rate was provided for each 1°×1° in latitude and longitude and every 1 km in altitude. The typical emission rate in the corridor region was 2-5 pptv hour$^{-1}$. The calculated value is denoted as ΔNO$_y$. For the present analysis, air masses in which the ΔNO$_y$ value was less than 40 pptv were used for the reference relationship irrespective of the location in which they were sampled. A large portion of the data in the O$_3$ = 100–200 ppbv range was obtained off the west coast of the US (flight on 971009). These air masses had been transported by westerly winds from locations over the Pacific ocean where aircraft emissions are climatologically not very high. The data obtained at latitudes lower than 45°N and higher than 60°N was also selected as background for both the UT and LS. The criterion of 40 pptv within 10-d used in this study was admittedly arbitrary and subjective. A value of 40 pptv was
chosen simply because enough data points in each O$_3$ range were selected by this criterion. However, the resultant estimates of aircraft effects were not very sensitive to the choice of this criterion as long as it was relatively small. If real background air masses were based on the criterion of $\Delta$NO$_y$ = 0 pptv, the data selected under the present criterion would underestimate the aircraft impact. When 40 pptv was chosen as the criterion, 42 and 37% of the UT and LS air masses sampled above 8.5 km were classified as background air masses. In air masses when the $\Delta$NO$_y$ values were lower or higher than 40 pptv, the median $\Delta$NO$_y$ value was 17 or 100 pptv, respectively, in the UT, suggesting a large difference in the effect of aircraft on the two sets of air masses. The same feature was also seen in the LS where the median value of $\Delta$NO$_y$ was 14 and 107 pptv. The median value of the NO$_y$ mixing ratio in the background air mass was then calculated for each 10 ppbv O$_3$ range and a linear relationship was calculated using these median values in the UT and LS separately as shown in Figure 4. The relationships in the UT and LS were smoothly connected at the O$_3$ value of 100 ppbv. Using the reference NO$_y$-O$_3$ relationship (referred as the "low $\Delta$NO$_y$ reference" hereafter), the expected NO$_y$ value in the background air mass was calculated using the O$_3$ value simultaneously observed. The difference between this expected NO$_y$ value and the observed NO$_y$ value was defined as an excess NO$_y$ (dNO$_y$).

For the second approach, the CN concentration was chosen as the criterion. This is because within the plume of the aircraft, enhancements of the CN value were often observed simultaneously with enhancements of the NO and NO$_y$ [Anderson et al., 1999]. Consequently, relatively higher CN values can be expected when an air mass is influenced by aircraft emissions. As shown in Figure 5, the CN concentration increased with altitude both in the UT and LS. These vertical profiles could partly be due to aircraft emissions which are most intensive at altitudes between 10 and 12 km. In fact, the analysis made by Kondo et al. [1999] showed that the CN fine particle concentration positively correlated with the NO$_x$ mixing ratio and NO$_x$/NO$_y$ ratio in the LS air masses obtained during SONEX. Moreover, the slope of the positive correlation between the CN and NO$_x$ values was generally close to the median value of the ratio between the enhanced levels of NO$_y$ (δNO$_y$) and CN (δCN) found in the aircraft plumes (δNO$_y$/δCN = 0.11 pptv STP-cm$^{-3}$). They concluded that an
increase in CN particles due to aircraft emissions constituted 29% of the observed CN fine particle concentration. These results suggest that air masses with low CN values can be used as background in the LS. A positive correlation between the CN concentration and NO$_x$/NO$_y$ ratio was also found in the UT in air masses with CN < 5000 STP-cm$^3$ (Figure 6). Although the overall correlation was partly due to the vertical profile of CN and NO$_x$/NO$_y$, a positive correlation was generally found even within each 1 km layer and within limited O$_3$ ranges. These results suggest that aircraft emissions played some role as a source of CN in the UT air masses sampled during SONEX. Using the SONEX data, Anderson et al. [1999] estimated that 8% of the CN fine particles in the northern hemispheric UT originated from aircraft emissions, based on the emission index of CN obtained within the aircraft plumes. However, it should be noted that when a clear enhancement of NO and NO$_y$ due to lightning activity was seen during the above-mentioned four flights, an enhancement of CN concentration up to 3$\times$10$^4$ STP-cm$^3$ was also seen. New particle formation in the cloud-scavenged air around cumulous clouds can elevate the CN concentration in the UT [e.g., Clarke et al., 1998]. Consequently, although low CN air masses were considered to be relatively unaffected by aircraft emissions, high CN air masses were not necessarily affected greatly. For the present analysis, air masses with a CN concentration lower than 1500 and 1000 STP-cm$^3$ were used to make a reference NO$_y$-O$_3$ relationship in the UT and LS, respectively, irrespective of the location in which they were sampled. A different criterion was chosen because the CN concentration was systematically higher in the UT than in the LS (Figure 5). These data corresponded to 28 and 47% of the UT and LS data. As for the “low $\Delta$NO$_y$ reference”, a median NO$_y$ value was calculated for each 10 ppbv O$_3$ range and a linear relationship was calculated for the UT and LS data separately (Figure 4, denoted as the “low CN reference” hereafter). The dNO$_y$ values were calculated for every 10-s data using this relationship.

3.2. Validity and Uncertainty in the dNO$_y$ Estimate

3.2.1. Reference values. The median values of the dNO$_y$ calculated using the two references are shown in Table 1 for both the UT and LS data. The median dNO$_y$ values for each 1 km layer are
also shown for the tropospheric data in the NAFC region (Figure 7). In this case, the \( \text{dNO}_x \) values were calculated down to 6.5 km, although the reference was derived using the data at 8.5 - 11.5 km. The two sets of \( \text{dNO}_x \) values were generally in good agreement when relatively large uncertainties were considered. Because the two definitions of the background air mass had quite different characteristics, the agreement between the two sets of \( \text{dNO}_x \) values confirmed the validity of the method adopted in this study. The \( \text{dNO}_x \) values calculated using the low CN reference were slightly lower when compared to those calculated using the low \( \Delta \text{NO}_y \) reference. The median of the differences in the \( \text{dNO}_x \) values was 8 and 18 pptv in the UT and LS, respectively, suggesting the uncertainty in the \( \text{dNO}_x \) estimation caused by selecting the background air mass. Since the difference in the two sets of the \( \text{dNO}_x \) values was small and systematic, the values calculated from the low \( \Delta \text{NO}_y \) reference are used in the following discussion. Although it is not shown here, similar results were also obtained when the \( \text{dNO}_x \) value was calculated using the \( \text{N}_2\text{O-NO}_x \) relationship in the LS instead of using the \( \text{NO}_y\text{-O}_3 \) one.

### 3.2.2. Correlation

In Figure 8, a correlation plot between \( \text{dNO}_x \) and \( \Delta \text{NO}_y \) is shown for the UT NAFC data (8.5 - 11.5 km). In this figure, the median \( \text{dNO}_x \) values for each 50 pptv range in the \( \Delta \text{NO}_y \) values and a one-to-one line are also shown. A large variability was generally seen in the \( \text{dNO}_x \) values presumably reflecting the wide variety of air mass histories. However the median values of \( \text{dNO}_x \) generally increased with the \( \Delta \text{NO}_y \) values suggesting that the averaged \( \text{dNO}_x \) values were reasonable estimates for the aircraft impact on reactive nitrogen. The \( \text{dNO}_x \) values were generally lower than the \( \Delta \text{NO}_y \) values, partly due to the fact that when the \( \Delta \text{NO}_y \) value was higher, the \( \text{NO}_y \) value in the real atmosphere tended to decrease more because of dilution.

On the other hand, the \( \text{dNO}_x \) value in the UT did not increase with either the \( \text{CO} \) or \( \text{C}_2\text{H}_2 \) value both in the NAFC and US continent regions (not shown), suggesting that the high \( \text{dNO}_x \) values were generally not due to the convective transport of polluted air masses.

### 3.2.3. Influence from lightning

One of the largest error sources, which can result in
overestimating the dNO\textsubscript{y} values in the UT, is influence from NO production by lightning. As described above, the data, which had a clear signature of NO production by lightning (i.e., distinct enhancement in the NO and NO\textsubscript{y} mixing ratios and the NO\textsubscript{x}/NO\textsubscript{y} ratio), was excluded from the present analysis. However, these were the only cases in which data were removed showing the influence of recent NO production by lightning. Lightning activity generally has an effect similar to aircraft emissions: it increases the NO\textsubscript{x} and NO\textsubscript{y} mixing ratios, the NO\textsubscript{x}/NO\textsubscript{y} ratio, and the CN concentration. In order to estimate the effect of aircraft on air masses which had been minimally affected by lightning, dNO\textsubscript{y} values were calculated using only air masses which had remained over the Atlantic Ocean more than 90 % of time within 5-d prior to the measurements. This criterion was used because most lightning activities occur over land [e.g. Turman and Edger 1982]. In addition, air masses which had passed near the Florida Peninsula were also excluded because of the intensive lightning activity in that region. The selected data consisted of 27 % of the UT data in the NAFC region. As a result, the median dNO\textsubscript{y} values in the 9.5-11.5 km range where the largest dNO\textsubscript{y} values were obtained decreased by 24 %. Because these air masses generally came from lower latitudes where aircraft NO\textsubscript{x} emissions were lighter, the reduction in dNO\textsubscript{y} values could also have been the result of the change in the effect of aircraft. However, this change in the dNO\textsubscript{y} value provides an estimate of the degree of possible overestimation of the effect of aircraft in this study.

3.2.4. Stagnated air mass within the NAFC region. A clear indication that aircraft emissions had caused an increase in dNO\textsubscript{y} was seen in air masses sampled during the flight made at the eastern NAFC region on 971023 (Figure 1). The correlation plot of NO\textsubscript{x}-dNO\textsubscript{y} obtained during this flight is shown in Figure 9. Most of the dNO\textsubscript{y} was found to be in the form of NO\textsubscript{x}, suggesting that the NO\textsubscript{x} input had been made within the lifetime of NO\textsubscript{x} of about 5 days (UT at 40N-60°N). The 10-day back trajectories of the air masses obtained during this flight are shown in Figure 10. As shown in this figure, these air masses remained over the ocean in last 10-d and stagnated in the NAFC region the last 5-d. The median value of the O\textsubscript{3} and CO mixing ratios in the UT (8.5-11.5 km) were 37 and 77 ppbv and they changed little throughout the flight. Consequently, most of the change
in NO\textsubscript{x} and NO\textsubscript{y} was quite likely due to aircraft emissions. The median and maximum value of the \( \Delta \text{NO}_y(10\text{-d}) \) were 71 and about 300 pptv, respectively, at altitudes between 9.5 and 11.5 km. Almost all of the input from aircraft was made within the last 5-d in this calculation. The median and maximum value of the dNO\textsubscript{y} were 42 and about 200 pptv, respectively, in the 9.5-11.5 km altitude range. These data clearly indicate that aircraft emissions can raise the levels of NO\textsubscript{x} and NO\textsubscript{y} over a large region and the effect was successfully detected by the method used in this study.

3.3. Vertical Profile of dNO\textsubscript{y}

In the NAFC region of the troposphere, the dNO\textsubscript{y} values were close to zero at altitudes between 7 and 9 km, suggesting minor impact from aircraft emissions (Figure 7). At altitudes above 9 km, dNO\textsubscript{y} increased with altitude, reaching 43 and 71 pptv at 10 and 11 km, respectively. (37 and 66 pptv at these two altitudes when the low CN reference was used.) The medians of the dNO\textsubscript{y}/NO\textsubscript{y} ratio at these two altitudes were 16 and 21%; i.e., about 20 \% of the NO\textsubscript{y} in the UT likely originated from aircraft emissions. These results are also summarized in Table 1.

As described above, the model input NO\textsubscript{x} value along the air mass trajectory, ANO\textsubscript{y}, was calculated for each data point. Consequently, a statistical analysis can be made on the ANO\textsubscript{y} value for the same data set from which the dNO\textsubscript{y} values were calculated. In Figure 7, the median values of ANO\textsubscript{y} for the 5-d and 10-d trajectories are shown. The median ANO\textsubscript{y}(10-d) was 25 pptv at 9 km and increased with altitude reaching 160 pptv at 11 km. The shape of the profile is consistent with the that of the dNO\textsubscript{y} value, although the dNO\textsubscript{y} values were systematically lower than the ANO\textsubscript{y} values, a likely result of the dilution effect.

The median value of dNO\textsubscript{y} in the UT over the US continent region was calculated using all of the data obtained at 8.5-11.5 km range (Figure 11 and Table 1). This was because the amount of the data was not sufficient to derive a vertical profile of the dNO\textsubscript{y} values. The median value was 32 pptv, comparable to the 28 pptv in the NAFC region. Although the data over the US continent was obtained from only two flights and the amount of data was smaller (4790 versus 1539 10-s data), the results here suggest a similar effect from aircraft emissions in the two regions.
The median value of dNO\textsubscript{y} in the LS was calculated for the 8.5-11.5 km range (Figure 11 and Table 1). The median values of dNO\textsubscript{y} and dNO\textsubscript{y}/NO\textsubscript{y} in the NAFC region were 128 pptv and 16 %, respectively. (110 pptv and 14 % when the low CN reference was used.) The median dNO\textsubscript{y} value over the US continent region was 89 pptv, again comparable to the NAFC value when the large central 67 % ranges are considered. It should be noted that these dNO\textsubscript{y} values were systematically higher than those in the UT both in the NAFC and US continent regions, 28 pptv versus 89 pptv in the NAFC region. The contrast in the dNO\textsubscript{y} values between the UT and LS was much higher than that in the ANO\textsubscript{y}(10-d) values, at least in the NAFC region (72 pptv versus 102 pptv). One possible explanation is the longer residence time of NO\textsubscript{y} in the LS than in the UT. In the UT, the NO\textsubscript{y} level can be lowered by dry and wet deposition of HNO\textsubscript{3} and aerosol nitrates through the vertical mixing of air. In the LS, NO\textsubscript{y} cannot be lost until the air mass is transported into the troposphere. Gettelman [1998] estimated the residence time was around 50-d for aircraft exhaust released in the LS (lowermost stratosphere) using the NASA 1992 zonal mean aircraft emission database. During SONEX, all the stratospheric air masses were sampled in the LS as described above. Since the tropopause height was lower during late autumn, a larger amount of NO\textsubscript{x} could have been injected into the LS and the LS air masses might have been influenced by the accumulated effect.

3.4. Relationship of dNO\textsubscript{y} with NO\textsubscript{x}/NO\textsubscript{y}, CN, and O\textsubscript{3}

In Figures 12a-12d, the correlation plots between the dNO\textsubscript{y}, NO\textsubscript{x}/NO\textsubscript{y}, CN, and O\textsubscript{3} values are shown for the UT and LS using the data from both the NAFC and the US continent regions. For these figures, we used only the data in which the model input NO\textsubscript{x} values during the last 5-d were greater than 80 % of the 10-d values (i.e., ANO\textsubscript{y}(5-d)/ANO\textsubscript{y}(10-d) > 0.8). This is because NO\textsubscript{x} molecules emitted from aircraft more than 5-d prior to the measurements could have already been converted to higher oxidized species, such as HNO\textsubscript{3}. In fact, this data selection generally improved the degree of correlation. The lifetime of NO\textsubscript{x} was estimated to be 4.8 and 3.2-d in the UT and LS (O\textsubscript{3}=100-200 ppbv), respectively, at 40°N – 60°N using the observed values of aerosol surface area etc. In Figure 12a, the dNO\textsubscript{y} values were plotted against the NO\textsubscript{x}/NO\textsubscript{y} ratios.
obtained in the UT. Different symbols were used for the data where $O_3 = 0$-50 ppbv and 50-100 ppbv, respectively. The $NO_x/NO_y$ ratio generally increased with $dNO_y$ in both data sets. This is consistent with the fact that emissions of $NO_x$ from aircraft increases both the $NO_x/NO_y$ ratio and $dNO_y$ value. In other words, the change in the $NO_x/NO_y$ ratio observed in the UT during SONEX was partly due to $NO_x$ from aircraft emissions. A positive correlation observed in the air masses where $O_3 = 0 - 50$ ppbv was mostly due to those sampled on 971023 which had been strongly affected by aircraft emissions as described above. The degree of the $NO_x/NO_y$ increase was higher for air masses where $O_3 = 0$-50 ppbv than that for air masses where $O_3 = 50$-100 ppbv when data with same $dNO_y$ value was compared. This result is plausible because the $NO_y$ value was generally lower when $O_3$ was low (Plate 1) and the $NO_x$ input could cause a greater change in the $NO_x/NO_y$ ratio.

In Figure 12b, $dNO_y$ values were plotted against the CN concentration obtained in the UT. Kondo et al. [1999] and Anderson et al. [1999] calculated the ratio between enhanced levels of $NO_y$ ($\delta NO_y$) and CN ($\delta CN$) observed within aircraft plumes. The $\delta NO_y/\delta CN$ ratio ranged between 0.04 and 0.2 pptv STP-cm$^3$ with a median value of 0.11 pptv STP-cm$^3$. In Figure 12b, two lines having this slope and different intercepts are also plotted. As seen in this figure, the $dNO_y$ value had a weak positive correlation with the CN concentration in both the air masses where $O_3 = 0$-50 ppbv and 50-100 ppbv. Based on the PCASP measurements, the median value of the aerosol surface area for aerosol particles with diameters between 0.1 and 3.0 $\mu$m was 1.7 $\mu$m$^2$ cm$^{-3}$ in the UT in the NAFC region. Under this condition, CN is lost primarily by the Brownian coagulation with CN, for CN concentrations higher than about 1400 STP-cm$^{-3}$. The half-lifetime of CN with a diameter of 15 nm at a CN concentration of 2500 STP-cm$^{-3}$ is 1.3 days and decreases inversely with the CN mixing ratio [Pruppacher and Klett, 1997; B.Liley, personal communication 1999]. Because the lifetime of CN was shorter than that of $NO_x$ and $NO_y$, the CN concentration should be generally lower than that expected from the slope in the aircraft plumes if aircraft emissions were the dominant source of CN. Consequently, the observed result was not inconsistent with the hypothesis that aircraft emissions contributed to a source of CN for air masses where $O_3 = 50$-100 ppbv. On the other hand, other CN
sources were predominant for air masses where $O_3 = 0 - 50$ ppbv, because much higher CN concentrations than those expected from aircraft emissions were observed in these air masses. In fact, no correlation between CN and NO$_x$/NO$_y$ was found for air masses where CN > 5000 STP-cm$^3$ as described above (Figure 6). However it should be noted that a positive correlation having a similar slope to that within the aircraft plumes was seen in a part of air masses. As described above, air masses sampled on 971023 had probably been strongly affected by aircraft emissions (see Subsection 3.2.4.) and the $O_3$ values in these air masses were mostly below 50 ppbv. The data where NO$_x$ was higher than 60 pptv obtained on this day were shown using a different symbol in Figure 12b and their CN-dNO$_y$ slope was found to be generally similar to that observed within the aircraft plumes. Consequently, aircraft emissions could have caused an increase in the CN concentration in the UT in some cases during SONEX, resulting in the positive correlation between CN and dNO$_y$, and CN and NO$_x$/NO$_y$, although the background level of the CN concentration was changed greatly by other CN sources.

In Figure 12c, the correlation plot between dNO$_y$ and the NO$_x$/NO$_y$ ratio in the LS is shown. A positive correlation was generally found in the LS. Because the LS air mass was generally free from tropospheric reactive nitrogen sources, the results shown here strongly suggest that an NO$_x$ input from aircraft emissions primarily caused the NO$_x$ variation in the LS.

In Figure 12d, the correlation plot between dNO$_y$ and CN in the LS is shown. A clear positive correlation between the two parameters was found suggesting that aircraft emissions were an important source of CN in the LS. The slope between dNO$_y$ and CN was generally smaller as compared to the median $\delta$NO$_y$/CN ratio of 0.11 pptv STP-cm$^3$ observed in aircraft plumes. This is reasonable because the lifetime of NO$_y$ is much longer than that of CN in the LS.

In Figures 13a and 13b, the correlation plots between dNO$_y$, O$_3$, and NO$_x$/NO$_y$ and O$_3$ are shown using both the UT and LS data in the NAFC region. The median values of dNO$_y$ or NO$_x$/NO$_y$ in seven O$_3$ ranges are also shown. Systematically large dNO$_y$ values were generally found with O$_3$ values between 75 and 125 ppbv. The dNO$_y$ values were generally distributed around zero for lower and higher O$_3$ air masses. These features are quite similar to those of the correlation plot between
NO\textsubscript{x}/NO\textsubscript{y} and O\textsubscript{3}, suggesting a relatively greater effect from aircraft emissions in the air masses with O\textsubscript{3} values between 75 and 125 ppbv. These air masses are considered to have remained generally around the tropopause altitude where NO\textsubscript{x} input from aircraft emissions is large. Air masses with a lower O\textsubscript{3} mixing ratio in the UT could generally be more strongly influenced by lower altitude air. This is consistent with the fact that the dNO\textsubscript{y} values were close to zero when the CO and C\textsubscript{2}H\textsubscript{2} values were high. Similarly, air masses with O\textsubscript{3} values higher than 125 ppbv are considered to be less affected by aircraft emissions. Further decreases in the NO\textsubscript{x}/NO\textsubscript{y} ratio with an increasing O\textsubscript{3} value between 125 and 300 ppbv were likely because the loss rate of NO\textsubscript{x} via heterogeneous hydrolysis of N\textsubscript{2}O\textsubscript{5} is higher for higher O\textsubscript{3} values. Similar O\textsubscript{3} dependence of the dNO\textsubscript{y} and NO\textsubscript{x}/NO\textsubscript{y} values was also seen in the air masses obtained over the US continent in the UT and LS. In this case, high NO\textsubscript{x}/NO\textsubscript{y} ratios up to 0.3 were observed with O\textsubscript{3} values as high as 160 ppbv.

3.5. Estimation of dNO\textsubscript{x} in the UT

The ratio between excess NO\textsubscript{x} (dNO\textsubscript{x}) and dNO\textsubscript{y} was estimated from the following expression:

\[
\frac{dNO_x}{dNO_y} = \frac{NO_x - NO_y}{NO_y} \cdot \sqrt{\frac{1}{1 - \frac{\gamma}{\gamma}}} \cdot \frac{1}{1 - \frac{\gamma}{\gamma}} \cdot (1)
\]

where \(\gamma = \frac{dNO_y}{NO_y}\). To make the reference NO\textsubscript{x}/NO\textsubscript{y} ratio, we used the background air masses what were used to make the reference NO\textsubscript{y}-O\textsubscript{3} relationship, i.e., air masses with \(\Delta NO_x(10-d)\) values (model NO\textsubscript{x} input along the 10-d back trajectory) lower than 40 pptv. In Figure 14, a vertical profile of the median NO\textsubscript{x}/NO\textsubscript{y} ratio in the background air masses is shown with that in air masses in the NAFC region. The NO\textsubscript{x}/NO\textsubscript{y} ratios in the NAFC region were systematically higher than those in the background air masses. Using these NO\textsubscript{x}/NO\textsubscript{y} values and the dNO\textsubscript{x}/dNO\textsubscript{y} values shown in Table 1 (low \(\Delta NO_x(10-d)\) reference), dNO\textsubscript{x}/dNO\textsubscript{y} was calculated for each 1 km altitude level. As a result, the dNO\textsubscript{x}/dNO\textsubscript{y} ratio was estimated to be 0.54 and 0.38 at altitudes of 10 and 11 km, respectively. Even if the median NO\textsubscript{x}/NO\textsubscript{y} values in the low CN air masses were used for the reference, similar results
were obtained (Figure 14). Furthermore, even if only the data at 45°N – 60°N were used for the reference to eliminate a possible effect from the change in the NOx/NOy ratio with latitude, similar results were obtained. These results suggest that about half of the excess NOy was likely to be in the form of NOx in the UT. Using an average dNOx/dNOy value of 0.46, we found the excess NOx to be 20 and 33 pptv at 10 and 11 km, respectively.

The dNOy/NOx ratio can be also expressed using the NOx/NOy ratio and dNOy/NOy ratio by transforming the equation (1). Using the same values shown above, we estimated that 30% of the NOx at 10 and 11 km was likely to have originated from aircraft emissions in the UT.
4. Summary

The large scale impact of aircraft emissions on reactive nitrogen in the UT and LS was estimated using the \( \text{NO}_y-\text{O}_3 \) correlation obtained during SONEX, which was carried out over the US continent and NAFC region in October and November 1997. For the present analysis, we excluded data obtained within aircraft plumes, data clearly influenced by NO production by lightning, and data influenced by recent convective transport of air affected by surface sources. Two reference \( \text{NO}_y-\text{O}_3 \) relationships in the air masses, which were considered to be affected little by aircraft emissions, were made using the data obtained above 8.5 km. First, the integrated input of \( \text{NO}_x \) into an air mass along a 10-d back trajectory (\( \Delta \text{NO}_y \)) was calculated based on the ANCAT/EC2 aircraft emission inventory. When the \( \Delta \text{NO}_y \) value was less than 40 pptv (lower 42 and 37 % values in the UT and LS), that air mass was used to make a reference \( \text{NO}_y-\text{O}_3 \) relationship, irrespective of the location from which it was sampled. Second, air masses with a CN concentration lower than 1500 and 1000 STP-cm\(^{-3}\) (lower 28 and 47 % values) in the UT and LS were used to make the reference. Using these two reference \( \text{NO}_y-\text{O}_3 \) relationships, the two sets of the excess \( \text{NO}_y \) (\( d\text{NO}_y \)) were calculated from observed values of \( \text{NO}_y \) and \( \text{O}_3 \).

The two sets of \( d\text{NO}_y \) values generally agreed within 8 and 18 pptv in the UT and LS, respectively, in spite of the very different nature of the criteria for the background air selection. The calculated \( d\text{NO}_y \) values did not positively correlate with either the CO values or anthropogenically produced hydrocarbons such as \( \text{C}_2\text{H}_2 \), suggesting a negligible effect of the surface sources on the \( d\text{NO}_y \) values. On the other hand, the weak positive correlation between the \( d\text{NO}_y \) and \( \Delta \text{NO}_y \) values indicated that the \( d\text{NO}_y \) values generally reflected the effect of aircraft emissions. By calculating the \( d\text{NO}_y \) values only for the air masses which remained over the ocean for 5-d prior to the measurement, the uncertainty in the \( d\text{NO}_y \) values due to the influence of recent NO production by lightning was estimated to be 24 %.

In the NAFC region (45\(^\circ\)N – 60\(^\circ\)N), the median value of \( d\text{NO}_y \) in the troposphere was close to zero between 7 and 9 km and increased with altitude above 9 km reaching 70 pptv (20 % of \( \text{NO}_y \)) at
High values of dNO$_y$ and NO$_x$/NO$_y$ ratio were generally found in air masses in which O$_3$ = 75 – 125 ppbv, suggesting a stronger effect around the tropopause. The median value of dNO$_y$ in the LS in the NAFC region at 8.5 – 11.5 km was about 120 pptv. The larger dNO$_y$ value observed in the LS was probably the result of the accumulated effect of aircraft emissions, given the long residence time of the affected air in the LS (50 days).

In general, the dNO$_y$ value positively correlated with the NO$_x$/NO$_y$ ratio in both the UT and LS in the NAFC and the US continent regions, suggesting that the observed large scale changes in the NO$_x$/NO$_y$ levels and NO$_x$ values in the UT and LS were partly caused by NO$_x$ from aircraft emissions. The slope of the positive correlation between the dNO$_y$ and CN values in the LS was generally consistent with that observed in the aircraft plumes, suggesting the importance of aircraft emissions as a source of CN in the LS. A positive correlation between the dNO$_y$ and CN values was also seen in a part of air masses in the UT and its slope was not inconsistent with that observed in the aircraft plumes; however, the significance of aircraft emissions is still not clear.

The ratio between excess NO$_x$ (dNO$_x$) and dNO$_y$ was calculated using the reference NO$_x$/NO$_y$ ratio. In the UT (NAFC region), it was estimated that about half of dNO$_y$ was in the form of NO$_x$ (20 and 33 pptv at 10 and 11 km) and about 30 % of the NO$_x$ had originated from aircraft emissions. These estimates were generally consistent with the results from the model calculations.

In this study, the degree of the large scale impact of aircraft emissions on reactive nitrogen was estimated from the observed data. A more quantitative estimate will be made using sophisticated three-dimensional models when they can consistently reproduce most of the observed features of various species.
Acknowledgments. We are indebted to all of the SONEX participants for their cooperation and support. Special thanks are due to the flight and ground crews of the NASA DC-8 for helping make this effort a success. We thank M. Kanada and H. Jindo for their technical assistance with the measurements of NO and NOy. We also thank B. Liley at NIWA, New Zealand, and L. Jaegle at Harvard University, for calculating the lifetime of CN and NOx, respectively. This work was supported in part by the Ministry of Education, Science, Sports, and Culture.

Figure 13

(a) Scatter plot of \( d\text{NO}_y \) (ppbv) vs. \( \text{O}_3 \) mixing ratio (ppbv), with error bars indicating variability.

(b) Scatter plot of \( \text{NO} / \text{NO}_y \) vs. \( \text{O}_3 \) mixing ratio (ppbv), showing a different parameter relation.

The plots illustrate the distribution and correlation of various atmospheric parameters, likely related to ozone and nitrogen oxides, with \( \text{O}_3 \) mixing ratio as a key variable.
