Rare Earth Optical Temperature Sensor

Donald L. Chubb and David S. Wolford
Glenn Research Center, Cleveland, Ohio
Since its founding, NASA has been dedicated to the advancement of aeronautics and space science. The NASA Scientific and Technical Information (STI) Program Office plays a key part in helping NASA maintain this important role.

The NASA STI Program Office is operated by Langley Research Center, the Lead Center for NASA's scientific and technical information. The NASA STI Program Office provides access to the NASA STI Database, the largest collection of aeronautical and space science STI in the world. The Program Office is also NASA’s institutional mechanism for disseminating the results of its research and development activities. These results are published by NASA in the NASA STI Report Series, which includes the following report types:

- **TECHNICAL PUBLICATION.** Reports of completed research or a major significant phase of research that present the results of NASA programs and include extensive data or theoretical analysis. Includes compilations of significant scientific and technical data and information deemed to be of continuing reference value. NASA's counterpart of peer-reviewed formal professional papers but has less stringent limitations on manuscript length and extent of graphic presentations.

- **TECHNICAL MEMORANDUM.** Scientific and technical findings that are preliminary or of specialized interest, e.g., quick release reports, working papers, and bibliographies that contain minimal annotation. Does not contain extensive analysis.

- **CONTRACTOR REPORT.** Scientific and technical findings by NASA-sponsored contractors and grantees.

- **CONFERENCE PUBLICATION.** Collected papers from scientific and technical conferences, symposia, seminars, or other meetings sponsored or cosponsored by NASA.

- **SPECIAL PUBLICATION.** Scientific, technical, or historical information from NASA programs, projects, and missions, often concerned with subjects having substantial public interest.

- **TECHNICAL TRANSLATION.** English-language translations of foreign scientific and technical material pertinent to NASA's mission.

Specialized services that complement the STI Program Office’s diverse offerings include creating custom thesauri, building customized data bases, organizing and publishing research results . . . even providing videos.

Rare Earth Optical Temperature Sensor

Donald L. Chubb and David S. Wolford
Glenn Research Center, Cleveland, Ohio

National Aeronautics and Space Administration

Glenn Research Center

January 2000
A new optical temperature sensor suitable for high temperatures ($\geq 1700$ K) and harsh environments is introduced. The key component of the sensor is the rare earth material contained at the end of a sensor that is in contact with the sample being measured. The measured narrow wavelength band emission from the rare earth is used to deduce the sample temperature. A simplified relation between the temperature and measured radiation was verified experimentally. The upper temperature limit of the sensor is determined by material limits to be approximately 2000 °C. The lower limit, determined by the minimum detectable radiation, is found to be approximately 700 K. At high temperatures 1 K resolution is predicted. Also, millisecond response times are calculated.

I. INTRODUCTION

There are a limited number of temperature sensors suitable for high temperatures (>1500 °C) and harsh environments. Platinum-rhodium type thermocouples, which can operate in reactive environments, are suitable for temperatures up to 1700 °C. However, similar to all thermocouples, they are not suitable for electrically hostile-environments. For temperatures beyond 1700 °C radiation thermometers are generally used. However, radiation thermometers require knowledge of the emissive properties of the sample being measured. For a sample with constant emittance (gray body) a radiation thermometer can be used without knowing the emittance. However, for a sample with an emittance that depends on the wavelength, a radiation thermometer is not suitable.

In this paper we report on a new optical temperature sensor suitable for high temperatures and harsh environments. This sensor does not require knowledge of the emissive properties of the sample being measured. The key to the operation of this sensor is the narrow band emission exhibited by rare earth ions (Re) such as ytterbium (Yb) and erbium (Er), in various host materials. Depending on the host material this sensor will operate at temperatures greater than 1700 °C.

Most atoms and molecules at solid state densities emit radiation in a continuous spectrum much like a blackbody. However, the rare earths, even at solid state densities, emit radiation in narrow bands much like an isolated atom. The reason this occurs is the following. For doubly (Re$^{2+}$) and triply charged (Re$^{3+}$) ions of these elements in crystals the orbits of the valence 4f electronics, which accounted for visible and near infrared emission and absorption, lie inside the 5s and 5p electron orbits. The 5s and 5p electrons "shield" the 4f valence electronics from the surrounding ions in the crystal. As a result, the rare earth ions in the solid state emit in narrow bands, much like the radiation from an isolated atom. The rare earths of most interest for the optical temperature sensor have emission bands in the near infrared (800 $\leq \lambda \leq$ 3000 nm).

Development of the rare earth optical temperature sensor has resulted from research on rare earth containing selective emitters for thermophotovoltaic (TPV) energy conversion. In that research we have found that rare earth doped yttrium aluminum garnet (Re$_x$Y$_{3-x}$Al$_5$O$_{12}$) where Re=Yb,Er,Tm or Ho is an excellent selective emitter. It is chemically stable at high temperatures (>1500 °C) and produces emittances of $e(\lambda) = 0.7$ in the emission bands.

In the following section the theory of the operation of the sensor is presented. Following that discussion, experimental results verifying the sensor operation will be presented. In the final section conclusions will be drawn.

II. THEORY OF OPERATION

Figure 1 is a schematic drawing for the rare earth optical temperature sensor. The sensor consists of 5 components; a rare earth containing end piece, an optical fiber, a narrow band optical filter, an optical detector, and electronics to convert the detector output to a temperature. The rare earth containing end piece, which is in contact with the sample to be measured, is attached to the optical fiber. Radiation from an emission band of the rare earth, which is proportional to the sample temperature, passes through the optical fiber to the bandpass filter. The
narrow band filter transmits to the detector only wavelengths within the emission band of the rare earth. Output from the detector is then converted to a temperature by an analog electronics package.

The upper temperature limit for this sensor will be determined by the temperature limits of the materials. If ytterbia (Yb₂O₃), which has a melting point of 2227 °C is used for the emitting end of the optical fiber then temperatures ≈2000 °C should be possible if a yttria (Y₂O₃, melting point = 2410 °C) optical fiber is used. If a sapphire (Al₂O₃) optical fiber is used then the upper limit is reduced since the melting point of sapphire is 2072 °C. These materials are chemically stable in atmosphere at high temperature.

A. Relation Between Temperature and Detector Output

Assuming the rare earth containing end piece emits uniformly over the area of the fiber, A, the radiation power, qᵣ(λ, Tₛ) entering the optical fiber from the rare earth at wavelength, λ, is the following.

$$qᵣ(λ, Tₛ) = ε_b(λ)e_B(λ, Tₛ)A \quad \text{W/ nm}$$ \hspace{1cm} (1)

Where $ε_b(λ)$ is the hemispherical spectral emittance into the optical fiber and $e_B(λ, Tₛ)$ is the blackbody emissive power at the temperature, $Tₛ$, of the rare earth containing end piece.

$$e_B(λ, Tₛ) = \frac{2πc₁}{λ^5[exp(c₂/λTₛ)−1]} \quad \text{W/ nm \cdot cm}^2$$ \hspace{1cm} (2)

$$c₁ = \frac{hc₀^2}{2π} = 5.9544 \times 10^{15} \quad \text{W \cdot nm}^4 / \text{cm}^2 \hspace{1cm} (3a)$$

$$c₂ = \frac{hc₀}{k} = 14.388 \times 10^6 \quad \text{nmK} \hspace{1cm} (3b)$$

Where $c₀$ is the speed of light in vacuum, $h$ is Planck’s constant and $k$ is Boltzmann’s constant.

We assume that the emission band of the rare earth is wider than the bandwidth ($λ_u ≤ λ ≤ λ_e$) of the optical filter. In other words, $ε_b(λ) > 0$ for $λ_u ≤ λ ≤ λ_e$. Also, the transmittance of the optical filter, $τ_f(λ) = 0$ for $λ_u > λ > λ_e$.

Therefore, if the optical filter transmittance is $τ_f(λ)$, then the power impinging on the detector, $q_d(λ, Tₛ)$, is the following.

$$q_d(λ, Tₛ) = τ_f(λ)τ_τ(λ)e_b(λ)e_B(λ, Tₛ)A \quad \text{F}_{id} \quad λ_u ≤ λ ≤ λ_e$$ \hspace{1cm} (4a)

$$q_d(λ, Tₛ) = 0 \quad λ_u > λ > λ_e$$ \hspace{1cm} (4b)

The term $F_{id}$ is the fraction ($F_{id} ≤ 1$) of the radiation that leaves the end of the optical fiber and reaches the detector. It is a geometrical factor that does not depend on $λ$ or $Tₛ$ and is called the view factor or configuration factor for the fiber to the detector. Included in $τ_τ(λ)$ is the loss of radiation that escapes out the sides of the optical fiber, as well as, absorption losses.

In using equation (4) for the radiation power arriving at the detector the following approximations are being made.

1. Radiation leaving rare earth containing end piece is uniform across $A$.
2. The filter transmittance, $τ_f$, optical fiber transmittance, $τ_τ$, and the spectral emittance, $ε_b$, depend only on wavelength.
3. Only radiation originating from the rare earth end piece reaches the detector.

If the rare earth containing end piece is of uniform thickness and at a uniform temperature in the direction parallel to the surface of the end piece then approximation 1 will be applicable. Since $qᵣ(λ, Tₛ)$ is small absorption in the optical filter and fiber will be small so that $τ_f$ and $τ_τ$ will be independent of $qᵣ(λ, Tₛ)$ and depend only on $λ$. However, if a
significant temperature drop ($\Delta T/T_s > 0.05$) occurs across the rare earth containing end piece then $\varepsilon_b$ will be a function of $T_s$, as well as, $\lambda$. To minimize this effect the rare earth containing end piece must be thin ($\leq 0.05$ cm), but not too thin. The emittance, $\varepsilon_b$, depends on the film thickness.\footnote{If the film is too thin ($< 0.005$ cm) the emittance will be reduced to a value such that $q_s$ is too small to be detected.} The indices of refraction of the optical fiber and rare earth containing end piece will change slightly with temperature. We neglect this effect on $\varepsilon_b$ and $\tau$.

If the sample being measured has large emittance within the emittance band of the rare earth then this sample radiation will contribute to $q_s$. This background radiation can be eliminated by placing a low emittance material such as platinum (Pt) between the sample and the rare earth containing end piece. In the experiment to be discussed in the next section, Pt foil was placed between the sample and the rare earth containing end piece. Any radiation, that impinges on the sides of the optical fiber will not reach the detector. This radiation will merely pass through the fiber in wavelength regions where the fiber is transparent or be absorbed in wavelength regions of high absorption ($\lambda > 5000$ nm for sapphire). None of this radiation will be refracted such that it can reach the detector as long as the index of refraction of the fiber is greater than the index of refraction of the surroundings.

Now consider the relation between the detector output and the temperature, $T_s$. A photovoltaic (PV) detector, such as silicon, is used to convert the radiation input into a current output. A photoconductive detector could also be used as the optical detector. However, a silicon PV detector was chosen because of its superior detectivity, time constant and low cost.\footnote{The equivalent circuit\footnote{By using a silicon PV detector we are assuming that the PV detector responds to all radiation within the limits ($\lambda_o < \lambda < \lambda_s$) of the optical filter. In other words, $Sr(\lambda) > 0$ for $\lambda_o < \lambda < \lambda_s$.} for a photovoltaic device is shown in figure 2. The current generated by the input radiation is $i_{ph}$, the current that flows if a potential $V$ is applied when the device is in the dark is $i_{dark}$, and the output current that flows through the load is $i$. The series resistance is $R_s$ and the shunt resistance is $R_{sh}$. Applying Kirchhoff's Law to the circuit loop containing $R_s$ and $R_{sh}$ yields the following.}

$$\begin{align*}
i = \frac{R_{sh}(i_{ph} - i_{dark}) - V_L}{R_{sh} + R_s}
\end{align*}$$

The dark current is the following.\footnote{The short circuit output current equals the photon generated current.}

$$i_{dark} = i_{sat}\left(\exp(aV/T_s) - 1\right)$$

Where $i_{sat}$ is the so-called saturation current, $e$ is the electric charge and $T_d$ is the temperature of the device. Since $V = V_L + iR_s$, equation (5) becomes the following.

$$i = \frac{1}{R_{sh} + R_s}\left(R_{sh}\left[i_{ph} - i_{sat}\left(\exp(aV_L/T_s)\exp(\alpha R_s/T_d) - 1\right)\right] - V_L\right)$$

Since this current output will be feed into an operational amplifier that acts like a short circuit ($V_L = 0$), the current is the following.

$$i_{sc} = \frac{R_{sh}}{R_{sh} + R_s}\left[i_{ph} - i_{sat}\left(\exp(\alpha R_s/T_d) - 1\right)\right]$$

We now assume that the photovoltaic detector has very small series resistance ($R_s \rightarrow 0$). This is a good approximation for silicon detectors. In that case the exponential term in equation (8) goes to one. Therefore, the current is the following.

$$i_{sc} = i_{ph} = \int_{\lambda_o}^{\lambda_s} Sr(\lambda)q_d(\lambda, T_s)d\lambda$$

Appearing in equation (10) is the spectral response of the PV detector, $Sr(\lambda)$, which gives the current generated per unit of radiation power incident on the PV detector. In using equation (10) we are assuming that the PV detector responds to all radiation within the limits ($\lambda_o < \lambda < \lambda_s$) of the optical filter. In other words, $Sr(\lambda) > 0$ for $\lambda_o < \lambda < \lambda_s$.
To proceed further we must have information on the wavelength dependence of $\tau_f$, $\tau$, $\varepsilon_b$ and $S_r$. The most simplification occurs if the bandwidth of the optical filter is so small that $\tau_f$, $\tau$, $\varepsilon_b$, $S_r$ and $\varepsilon_B$ are constant for $\lambda_u \leq \lambda \leq \lambda_v$. In that case equation (11) becomes the following.

$$i_{sc}(T_s) = A_F \tau_f \tau \varepsilon_b S_r \left[ \frac{2\pi c_1}{\exp(c_2/\lambda_f T_s)-1} \right] \left[ \frac{\lambda_f - \lambda_{ul}}{\lambda_f^2} \right] \exp\left(-c_2/\lambda_f T_s\right)$$

(12)

Where $\lambda_f = (\lambda_u + \lambda_v)/2$ is the center wavelength of the optical filter. For most all applications $\lambda_f < 2000$ nm and $T_s < 2500$ K. Therefore, $c_2/\lambda_f T_s > 2.88$ and $\exp(c_2/\lambda_f T_s) \gg 1$. Also, $A_d F_d = A_F d^2$, where $A_d$ is the detector area and $F_d$ is the detector to optical fiber view factor. In that case equation (12) becomes the following.

$$i_{sc}(T_s) = 2\pi c_1 A_d F_d \tau_f \tau \varepsilon_b S_r \left[ \frac{\lambda_f - \lambda_{ul}}{\lambda_f^2} \right] \exp\left(-c_2/\lambda_f T_s\right)$$

(13)

Solving this equation for $1/T_s$ yields the following result.

$$\frac{1}{T_s} = \frac{\lambda_f}{c_2} \left[ \ln C - \ln i_{sc}(T_s) \right]$$

(14)

Where,

$$C = 2\pi c_1 A_d F_d \tau_f \tau \varepsilon_b S_r \left[ \frac{\lambda_f - \lambda_{ul}}{\lambda_f^2} \right]$$

(15)

The constant $C$, which is independent of $T_s$, can be determined by a calibration procedure. At some known calibration temperature, $T_c$, the short circuited current $i_{sc}(T_c)$ is measured. Therefore,

$$\ln C = \frac{c_2}{\lambda_f T_c} + \ln i_{sc}(T_c)$$

(16)

and

$$T_s = \left[ \frac{1}{T_c} + \frac{\lambda_f}{c_2} \left( \ln i_{sc}(T_c) - \ln i_{sc}(T_s) \right) \right]^{-1}$$

(17)

Therefore, with the appropriate analog electronics the measured short circuit current, $i_{sc}$, of the PV detector can be converted to a temperature, $T_s$.

Remember that equation (17) was derived assuming that $\tau_f$, $\tau$, $\varepsilon_b$ and $S_r$ are constants for $\lambda_u \leq \lambda \leq \lambda_v$. This is a good approximation for the optical fiber transmittance, $\tau$. The reason being that the most probable optical fibers for high temperature are sapphire or yttria ($Y_2O_3$) which have nearly constant transmittance for wavelengths of interest ($800 \leq \lambda \leq 2000$ nm). It is not a good approximation to assume $\tau_f$, $\varepsilon_b$, and $S_r$ are independent of $\lambda$. However, as shown in appendix A where wavelength dependence of $\tau_f$, $\varepsilon_b$ and $S_r$ is included the short circuit current, $i_{sc}$, can be closely approximated by the following expression.
\[ i_{sc} = C_0 \exp\left[ -\frac{c_2}{\lambda_f T_s} \right] \]  

(18)

Where \( C_0 \) is independent of \( T_s \) and depends on \( \tau(\lambda_f), \varepsilon_b(\lambda_f) \) and \( S(\lambda_f) \), where \( \lambda_f \) is the center wavelength of the optical filter. As a result, equation (17) applies even when wavelength dependence of \( \tau, \varepsilon_b \) and \( S \) are included. If the bandwidth, \( \Delta \lambda_f \), of the optical filter is too large (\( \Delta \lambda_f > 25 \text{ nm} \)) then \( C_0 \) will depend on \( T_s \). Therefore, making \( \Delta \lambda_f \) small results in \( C_0 \) being nearly independent of \( T_s \). For a hypothetical sensor that uses a ytterbium containing emitter, which has an emission band centered at \( \lambda_e = 955 \text{ nm} \), and an optical filter with \( \lambda_f = 950 \text{ nm} \) and \( \Delta \lambda_f = 10 \text{ nm} \) the parameter \( C_0 \) varies less than 0.65 percent for \( 620 \leq T_s \leq 2500 \text{ K} \). If the filter bandwidth \( \Delta \lambda_f = 25 \text{ nm} \) then \( C_0 \) varies less than 3.0 percent for the same temperature range. As the results in Appendix A show the variation in \( C_0 \) for high temperatures (\( 1220 \leq T_s \leq 2500 \text{ K} \)) is much less. For the \( \Delta \lambda_f = 10 \text{ nm} \) filter the variation is less than 0.1 percent and for the \( \Delta \lambda_f = 25 \text{ nm} \) filter the variation is less than 0.5 percent.

B. Temperature Error

Consider the temperature error that results from using equation (18) for the short circuit current. Let \( i_{sc}(T_s) \) be the short circuit current corresponding to the true temperature, \( T_s \). Let \( i_{sc}(T_{se}) \) be the short circuit current that has a corresponding temperature, \( T_{se} \), and is in error from the true short circuit current, \( i_{sc} \), by the factor, \( p \). As a result the following expression applies.

\[ i_{se}(T_{se}) = p i_{sc}(T_{st}) \]  

(19)

Using equation (19) and equation (17) the following result is obtained for the error in temperature, \( (T_{st} - T_{se})/T_{st} \).

\[ \frac{T_{st} - T_{se}}{T_{st}} = \frac{\lambda_f}{c_2} \frac{T_{st}}{T_{st}} \ln p \]  

And since \( \lambda_f/c_2 T_{st} \ln p \ll 1 \),

\[ \frac{T_{st} - T_{se}}{T_{st}} = -\frac{\lambda_f}{c_2} T_{st} \ln p \]  

(20)

In the case of the \( \Delta \lambda_f = 25 \text{ nm} \) and \( \lambda_f = 950 \text{ nm} \) optical filter just discussed, the maximum error in \( i_{sc} \) that results from using equation (18) is less than 3 percent for \( 620 \leq T_s \leq 2500 \text{ K} \). Therefore, \( p = 0.97 \) and

\[ \frac{T_{st} - T_{se}}{T_{st}} < 2.0 \times 10^{-6} T_{st} \quad 620 \leq T_s \leq 2500 \text{ K} \quad \lambda_f = 950 \text{ nm}, \Delta \lambda_f = 25 \text{ nm} \]  

(21)

Therefore, if \( T_{st} = 2500 \text{ K} \) then \( T_{st} - T_{se} < 12.6 \text{ K} \) is the maximum possible error in \( T_s \) for \( \Delta \lambda_f = 25 \text{ nm} \) optical filter for \( 620 \leq T_s \leq 2500 \text{ K} \). For the \( \Delta \lambda_f = 10 \text{ nm} \) and \( \lambda_f = 950 \text{ nm} \) optical filter the maximum error in \( i_{sc} \) is less than 0.65 percent for \( 620 \leq T_s \leq 2500 \text{ K} \). Therefore, \( p = 0.9935 \) and

\[ \frac{T_{st} - T_{se}}{T_{st}} < 4.3 \times 10^{-7} T_{st} \quad 620 \leq T_s \leq 2500 \text{ K} \quad \lambda_f = 950 \text{ nm}, \Delta \lambda_f = 10 \text{ nm} \]  

(22)

For \( T_{st} = 2500 \text{ K} \) the maximum possible error in \( T_s \) is \( T_s - T_{se} < 2.7 \text{ K} \). If we restrict the temperature range to \( 1220 \leq T_s \leq 2500 \text{ K} \) then \( p = 0.995 \) for the \( \Delta \lambda_f = 25 \text{ nm} \) filter and \( p = 0.999 \) for the \( \Delta \lambda_f = 10 \text{ nm} \) filter. As a result the following results are obtained.
T_{st} - T_{sc} < 2.1K \quad \lambda_f = 950 \text{ nm}, \Delta \lambda_f = 25 \text{ nm} \quad (23a)

T_{st} = 2500K

T_{st} - T_{sc} < 0.4K \quad \lambda_f = 950 \text{ nm}, \Delta \lambda_f = 10 \text{ nm} \quad (23b)

\hspace{1cm} T_{st} = 2500K

From these results we conclude that temperature errors resulting from the use of equation (18) for \( i_{sc} \) will be less than 1K for a temperature sensor that uses the \( \lambda_f = 950 \text{ nm}, \Delta \lambda_f = 10 \text{ nm} \) filter over most of the useful temperature range.

C. Temperature Limits

What is the useful temperature range of the sensor? The upper temperature limit is set by the durability of the material and has already been discussed. However, the lower temperature limit is set by the minimum short circuit current, \( i_{sc} \), that can be measured. To estimate this lower temperature limit we make use of the results of appendix A. Assume that the optical filter and Yb containing emitter have the following characteristics, \( \lambda_f = 950 \text{ nm}, \Delta \lambda_f = 10 \text{ nm} \), \( \tau_{\text{MAX}} = 0.35, \lambda_E = 955 \text{ nm}, \alpha' = 0.8, \epsilon' = 0.01 \). Also assume a silicon detector of 1 mm in diameter \( (r_d = 0.05 \text{ cm}) \) and maximum spectral response \( S(\lambda_o) = 0.5 \text{ A/W} \), where \( \lambda_o = 1100 \text{ nm} \) is the wavelength that corresponds to the silicon bandgap energy, \( E_f = 1.1 \text{ eV} \). In addition, assume the optical fiber transmittance is \( \tau = 0.2 \) and the optical fiber diameter is approximately the same as the detector diameter and is as close as possible to the detector so that the detector to optical fiber view factor is \( F_v = 0.5 \). In that case the results from appendix A yield \( C_o = 5.8 \text{ A} \). The minimum value \( i_{sc} \) that can be detected will be determined by the electronics package and the electronic noise in the system. Using operational amplifiers in the electronics package should allow minimum short circuit currents of \( i_{sc} = 10^{-6} \text{ A} \) to be easily detected. In that case the results from appendix A yield \( T_s = 750 \text{ K} \). Obviously, at a given temperature a larger value of \( \Delta \lambda_f \) will result in larger \( C_o \) and therefore larger \( i_{sc} \). Thus, for \( \Delta \lambda_f = 25 \text{ nm} \) with all other conditions the same yields \( C_o = 13.8 \text{ A} \) and a temperature limit of \( T_s = 720 \text{ K} \). However, it must be remembered that \( \Delta \lambda_f = 25 \text{ nm} \) results in a larger error in \( T_s \) than the \( \Delta \lambda_f = 10 \text{ nm} \) case.

Based on the results just discussed, a lower temperature limit of the order of 700 \text{ K} should be possible with a silicon detector and optical fiber of 1 mm diameter. Using a larger diameter optical fiber and detector will result in a lower temperature limit. However, the larger optical fiber will also result in a larger temperature error since thermal conduction away from the sample will be larger.

D. Response Time

The time behavior of the output of the rare earth containing end piece of the sensor, \( q_s \), depends on how fast the end piece reaches a steady state temperature after a change in the sample temperature, \( T_s(t) \). This response time, \( \tau \), will be much larger than the transmission time of \( q_s \) through the optical fiber and filter since they occur at the speed of light. The response time of the detector and electronics should also be much smaller than \( \tau \). Therefore, the response time of the end piece, \( \tau \), will determine the response time of the sensor.

Assume the end piece behaves in a one-dimensional manner so that its temperature is governed by the one-dimensional heat conduction equation.

\[
k_{th} \frac{\partial^2 T}{\partial x^2} + \rho c_p \frac{\partial T}{\partial t} = 0
\]

(24)

Where \( t \) is time, \( x \) is the coordinate perpendicular to cross sectional area, \( A_1 \), of the end piece, \( k_{th} \) is the thermal conductivity, \( \rho \) is the density and \( c_p \) is the specific heat. If equation (24) is written in dimensionless form using dimensionless length \( \bar{x} = x/d \), where \( d \) = thickness of the end piece then we find that the appropriate dimensionless time is \( \bar{t} = t/\tau_o \) where,
In reference 7 solutions to equation (24) are presented for various boundary conditions and initial conditions. In all cases the time dependence is the following, where $\alpha$ is a constant.

$$\tau_0 = \frac{\rho c_p d^2}{k_{th}}$$  \hspace{1cm} (25)$$

This same result can be obtained by using the method of separation of variables on equation (24). The constant $\alpha$ depends on the boundary conditions and is the order of 1. Therefore, equation (25) can be used to estimate the response time, $\tau$, of the sensor.

Equation (25) indicates the response time is a quadratic function of $d$ so that by making the end piece thin the response time will be small. Assume that the end piece is a rare earth oxide such as ytterbia (Yb$_2$O$_3$) or erbium (Er$_2$O$_3$). Then $\rho < 10$ gm/cm$^2$ and $c_p < 1$ J/gmK. There is no data available on the thermal conductivity, $k_{th}$, or the rare earth oxides at high temperature. However, we expect they will have low thermal conductivity similar to other ceramic materials such as alumina where $k_{th} = 0.1$ W/cmK. Therefore, assume $k_{th} \geq 0.05$ W/cmK so that equation (25) yields the following for the response time, $\tau$.

$$\tau < 200 \text{ d}^2 \text{ sec} \text{ d in cm}$$  \hspace{1cm} (27)$$

Thus, if the minimum thickness end piece is $d = 0.005$ cm then the response time is $\tau < 5$ msec. As discussed earlier, the response time of the sensor should be determined by the end piece response time, $\tau$.

III. EXPERIMENTAL VERIFICATION OF SENSOR OPERATION

To verify that equation (17) applies for determining the temperature, $T_s$, the experiment shown in figure 3 was used. The sensor consists of a 0.055 cm diameter sapphire fiber with an erbium aluminum garnet (Er$_3$Al$_5$O$_{12}$) emitter of thickness, $d = 0.03$ cm attached with platinum (Pt) foil. Erbium has an emission band at $\lambda = 1000$ nm. The Pt foil serves two purposes. First of all it holds the emitter to the end of the fiber and secondly it blocks all radiation from the sample being measured. The thin (=0.005 cm) Pt foil will produce negligible temperature change between the sample and the emitter. In this case the sample being measured is Pt foil with a type R platinum versus platinum (13 percent) rhodium thermocouple attached behind the Pt foil. The Pt sample is held with an alumina holder, which is located in the center of a high temperature atmospheric furnace. At the other end of the sapphire fiber is a chopper and monochromator, which serves as the optical filter with a bandwidth of $\Delta\lambda = 2$ nm. A silicon detector converts the radiation leaving the monochromator to a short circuit current, $i_c$, which is measured with a lock-in amplifier.

The experimental procedure to verify equation (17) was as follows. First $i_{sc}(T_s)$ was determined by measuring $i_{sc}$ when the thermocouple was at temperature $T_c$. Knowing $i_{sc}(T_s)$, $T_s$, and $T_c = 1012$ nm, equation (17) was then used to calculate $T_s$ for a series of different thermocouple temperatures, $T_{TC}$. If equation (17) is valid then $T_s(T_c) = T_{TC}$. In figure 4 the sample temperature, $T_s$, calculated from equation (17) is plotted as a function of the thermocouple temperature, $T_{TC}$, for two different ranges. In figure 4(a) the range is $863 < T_{TC} < 1430$ K and in figure 4(b) the range is $1334 < T_{TC} < 1879$ K.

As figure 4 shows the agreement between $T_s$ and $T_{TC}$ is excellent. The largest error, $err = |T_{TC} - T_s|/T_{TC}$, occurs at the lowest temperatures. For figure 4(a), $err_{MAX} = 0.03$ and for figure 4(b), $err_{MAX} = 0.008$. As a result of this close agreement between $T_s$ and $T_{TC}$ we conclude that equation (17) is valid for determining the sample temperature, $T_s$, from the measured short circuit current, $i_{sc}$.

Figure 5 shows the lock-in amplifier output, which is directly proportional to the short circuit current, $i_{sc}$, as a function of $T_s$ for the same conditions as figure 4(b). Two things should be noted. First of all, because of the exponential dependence of $i_{sc}$ on $T_s$ (eq. (18)) the sensor sensitivity increases with temperature. As figure 5 shows for high temperatures (>1100K) a small change in $T_s$ results in a several millivolt change in amplifier output. Thus, we expect 1K temperature resolution at high temperature. The second thing to note is even though the monochromator bandwidth is small (=2 nm), the amplifier output is many millivolts. Therefore, the electronic circuit
that converts $i_{sc}$ to $T_e$ (eq. (17)) will operate with a large input signal, which should eliminate electronic noise problems.

IV. CONCLUSION

The operation of the rare earth optical temperature sensor has been experimentally verified. For the temperature range $863 \leq T \leq 1430K$ the maximum temperature deviation of the sensor temperature from a measured thermocouple temperature was 3 percent. For the temperature range $1334 \leq T \leq 1879K$ this error was reduced to 0.8 percent. Calculations show that a simple relation (eq. (18)) between temperature and detector output can be used to determine the temperature. The error resulting from using this relation will be less than 1K.

Material durability limits the upper temperature of the sensor. Using a yttria optical fiber and rare earth oxide emitters the upper temperature limit should be approximately 2000 °C. The lower temperature limit is determined by the minimum signal that can be detected. This limit is calculated to be approximately 700 K if a silicon detector is used.

Response time of the detector will be determined by how fast the emitter responds to a temperature change. This response time was estimated using the equation for thermal conduction. Results indicate that response times the order of msec are possible. Because of the exponential dependence of sensor output on the temperature we expect temperature resolution of 1 K to be possible.

The electronics package to convert the sensor output to a temperature is under development. This electronics package can be designed using commercially available parts. Thus the most expensive component of the sensor is expected to be the optical fiber.
APPENDIX A. RELATION BETWEEN TEMPERATURE AND DETECTOR SHORT CIRCUIT CURRENT

The complete relationship between the sample temperature, $T_s$, and the PV detector short circuit current is given by equation (11).

$$i_{sc}(T_s) = 2\pi c_1 A_f F_{cd} \int_{\lambda_0}^{\lambda_f} \tau_f(\lambda)\tau_e(\lambda)e_b(\lambda)Sr(\lambda) \frac{d\lambda}{\lambda^3[\exp(c_2/\lambda T_s) - 1]}$$  \hspace{1cm} (11)

As stated in the discussion about equation (17), it is a good approximation to assume the optical fiber transmittance, $\tau(\lambda)$, is constant for $\lambda_c \leq \lambda \leq \lambda_s$. The spectral response of a PV detector can be approximated as a linear function of wavelength.$^9$

$$Sr(\lambda) = \frac{\lambda}{\lambda_g} Sr_g \frac{A}{W} \hspace{1cm} 0 \leq \lambda \leq \lambda_g$$

$$Sr(\lambda) = 0 \hspace{1cm} \lambda_g < \lambda$$

Where $Sr_g$ is the spectral response at $\lambda = \lambda_g = h\nu_0/E_g$ and $E_g$ is the bandgap energy of the PV detector. A linear approximation can also be used for the spectral emittance, $\varepsilon_b(\lambda)$, of the rare earth selective emitter$^2$ for a narrow wavelength region around an emission band centered at $\lambda = \lambda_E$ that is located within the transmission band $\lambda_u \leq \lambda \leq \lambda_s$ of the optical filter.

$$\varepsilon_b(\lambda) = \varepsilon_{MAX} - \varepsilon'(\lambda - \lambda) \hspace{1cm} \lambda_u \leq \lambda \leq \lambda_E$$

$$\varepsilon_b(\lambda) = \varepsilon_{MAX} - \varepsilon'(\lambda - \lambda_E) \hspace{1cm} \lambda_E \leq \lambda \leq \lambda_s$$

Where $\varepsilon_{MAX} = \varepsilon(\lambda_E)$ is the maximum emittance and $\varepsilon'$ is the slope of the linear $\varepsilon_b(\lambda)$ versus $\lambda$ approximation. For a narrow bandwidth interference filter the transmittance, $\tau_f(\lambda)$, can be closely approximated by a Gaussian function.

$$\tau_f(\lambda) = \tau_{MAX} \exp\left[-\ln^2\frac{2(\lambda - \lambda_f)^2}{\Delta\lambda_f}\right]$$  \hspace{1cm} (A3)

Where $\lambda_f$ is the center wavelength of the transmission band, $\tau_{MAX} = \tau(\lambda_f)$, and $\Delta\lambda_f$ is the bandwidth defined by the wavelengths $\lambda_0 = \lambda_f - \Delta\lambda_f/2$ and $\lambda_s = \lambda_f + \Delta\lambda_f/2$ where $\tau(\lambda_f \pm \Delta\lambda_f/2) = \tau_{MAX}/2$. Figure A1 compares the experimental transmittance of an interference filter with $\lambda_f = 949$ nm and $\Delta\lambda_f = 14$ nm with equation (A3). As can be seen the agreement is quite good.

Figure A2 shows the approximations for $Sr(\lambda)/Sr_g$, $\varepsilon_b(\lambda)/\varepsilon_{MAX}$, and $\tau_f(\lambda)/\tau_{MAX}$ given by equations (A1), (A2) and (A3) for the case where $\lambda_f = 950$ nm, $\Delta\lambda_f = 10$ nm, $\lambda_E = 955$ nm, $\varepsilon_{MAX} = 0.8$, $\varepsilon'(\nu) = 0.01$ nm$^{-1}$ (ytterbium) and $\lambda_g = 1100$ nm (silicon). These approximations were used in equation (11) and $i_{sc}$ was calculated by numerical integration. The integration limits were $\lambda = \lambda_f - 4\Delta\lambda_f$ and $\lambda_s = \lambda_f + 4\Delta\lambda_f$, which insures that at these limits the integrand in equation (11) vanishes. To determined if equation (18) is a valid approximation for $i_{sc}$ we calculated $C_o$ in equation (18).

$$C_o = i_{sc} \exp\left[c_2/\lambda_f T_s\right]$$  \hspace{1cm} (A4)

Where $i_{sc}$ in equation (A4) is obtained by numerical integration of equation (11).

Figure A3(a) shows $C_o$ as a function of $T_s$ for the $\Delta\lambda_f = 10$ nm filter ($\lambda_f = 950$ nm, $\tau_{MAX} = 0.35$), fiber transmittance, $\tau = 0.2$ and the ytterbium emitter ($\lambda_E = 955$ nm, $\varepsilon_{MAX} = 0.8$, $\varepsilon'(\nu) = 0.01$ nm$^{-1}$) and silicon detector.
($\lambda_g = 1100$ nm, $S_{rg} = 0.5$ A/W). As can be seen, $C_0$ changes only by a small amount for $620 \leq T_i \leq 2500$ K. Thus, $C_0$ is nearly independent of $T_i$ and equation (18) is a valid approximation for $i_c$. Figure A3(b) shows $C_0$ for the case where $\Delta \lambda_r = 25$ nm with all other conditions being the same as in figure A3(a). In this case $C_0$ changes more than the $\Delta \lambda_r = 10$ nm case, but equation (18) should still be a good approximation for $i_c$. If the optical filter and emission band are matched ($\lambda_r = \lambda_e$) then $C_0$ varies even less over the temperature range ($620 \leq T_i \leq 2500$ K). For the $\Delta \lambda_r = 10$ nm filter the maximum variation in $C_0$ is less than 0.65 percent if $\lambda_E = 955$ nm and $\lambda_r = 950$ nm but is only 0.33 percent if $\lambda_r = \lambda_E = 955$ nm.

**Abstract:**
A new optical temperature sensor suitable for high temperatures (>1700 K) and harsh environments is introduced. The key component of the sensor is the rare earth material contained at the end of a sensor that is in contact with the sample being measured. The measured narrow wavelength band emission from the rare earth is used to deduce the sample temperature. A simplified relation between the temperature and measured radiation was verified experimentally. The upper temperature limit of the sensor is determined by material limits to be approximately 2000 °C. The lower limit, determined by the minimum detectable radiation, is found to be approximately 700 K. At high temperatures 1 K resolution is predicted. Also, millisecond response times are calculated.
