MARANGONI EFFECTS ON NEAR-BUBBLE MICROSCALE
TRANSPORT DURING BOILING OF BINARY FLUID MIXTURES

ABSTRACT

In earlier investigations (see Ahmed, et al. [1]), Marangoni effects were observed to be the
dominant mechanism of boiling transport in 2-propanol/water mixtures under reduced gravity
conditions. In this investigation we have examined the mechanisms of binary mixture boiling by
exploring the transport near a single bubble generated in a binary mixture between a heated
surface and cold surface. The temperature field created in the liquid around the bubble produces
vaporization over the portion of its interface near the heated surface and condensation over
portions of its interface near the cold surface. Experiments were conducted using different
mixtures of water and 2-propanol under 1g conditions and under reduced gravity conditions
aboard the KC135 aircraft. Since 2-propanol is more volatile than water, there is a lower
concentration of 2-propanol near the hot surface and a higher concentration of 2-propanol near
the cold plate relative to the bulk quantity. This difference in interface concentration gives rise to
strong Marangoni effects that move liquid toward the hot plate in the near bubble region for 2-
propanol and water mixtures. In the experiments in this study, the pressure of the test system
was maintained at about 5 kPa to achieve the full spectrum of boiling behavior (nucleate boiling,
critical heat flux and film boiling) at low temperature and heat flux levels. Heat transfer data and
visual documentation of the bubble shape were extracted from the experimental results.

In the 1-g experiments at moderate to high heat flux levels, the bubble was observed to grow into
a mushroom shape with a larger top portion near the cold plate due to the buoyancy effect. The
shape of the bubble was somewhat affected by the cold plate subcooling and the superheat of the
heated surface. At low superheat levels for the heated surface, several active nucleation sites
were observed, and the vapor stems from them merged to form a larger bubble. The generation
rate of vapor is moderate in this regime and the bubble shape is cylindrical in appearance. In
some instances, the bubble interface appeared to oscillate. At higher applied heat flux levels, the
top of the bubble became larger, apparently to provide more condensing interface area adjacent to
the cold plate. Increasing the applied heat flux ultimately led to dry-out of the heated surface,
with conditions just prior to dryout corresponding to the maximum heat flux (CHF). A more
stable bubble was observed when the system attained the minimum heat flux (for film boiling). In
this regime, most of the surface under the bottom of the bubble was dry with nucleate boiling
sometimes occuring around the contact perimeter of the bubble at heated surface. Figure 1 shows
a typical bubble in this regime.
Different variations (e.g. gap between two plates, molar concentration of the liquid mixture) of the experiments were examined to determine parametric effects on the boiling process and to determine the best conditions for the KC135 reduced gravity tests. Variation of the gap was found to have a minor impact on the CHF. However, reducing the gap between the hot and cold surface was observed to significantly reduce the minimum heat flux for fixed molar concentration of 2-propanol.

In the reduced gravity experiments aboard the KC135 aircraft, the bubble formed in the 6.4 mm gap was generally cylindrical or barrel shaped and it increased its extent laterally as the surface superheat increased. In reduced gravity experiments, dryout of the heated surface under the bubble was observed to occur at a lower superheated temperature than for 1g conditions. Observed features of the boiling process and heat transfer data under reduced gravity will be discussed in detail. The results of the reduced gravity experiments will also be compared to those obtained in comparable 1g experiments.

In tandem with the experiments we are also developing a computational model of the transport in the liquid surrounding the bubble during the boiling process. The computational model uses a level set method [2] to model motion of the interface. It will incorporate a macroscale treatment of the transport in the liquid gap between the surfaces and a microscale treatment of transport in the regions between the bubble interface and the solid surfaces. The features of the model will be described in detail. Future research directions suggested by the results to date will also be discussed.

\[ t = 21.018 \, s \]

\[ t = 22.026 \, s \]

\[ t = 23.414 \, s \]
Results of Experiments

- Two boiling modes observed:
  - Nucleate boiling
  - Large stationary bubble with partial surface dryout

- Phase morphology and heat transfer characteristics determined for each type
Subsequent Work

- Development of model of near-bubble transport including
  - Wall conduction
  - Bulk fluid motion
  - Microlayer transport between interface and walls
  - Marangoni effects

- Comparison of experimental data with model predictions for 1g and reduced g results
- Analysis of parametric effects using model
- Experiments with other aqueous mixtures
