Chapter 1
Introduction and Summary

This report documents efforts to analyze a sample of aviation safety programs, using the LMI-developed integrated safety analysis tool to determine the change in system risk resulting from Aviation Safety Program (AvSP) technology implementation. Specifically, we have worked to modify existing system safety tools to address the safety impact of synthetic vision (SV) technology. Safety metrics include reliability, availability, and resultant hazard. This analysis of SV technology is intended to be part of a larger effort to develop a model that is capable of "providing further support to the product design and development team as additional information becomes available." The reliability analysis portion of the effort is complete and is fully documented in this report. The simulation analysis is still underway; it will be documented in a subsequent report.

The specific goal of this effort is to apply the integrated safety analysis to SV technology. This report also contains a brief discussion of data necessary to expand the human performance capability of the model, as well as a discussion of human behavior and its implications for system risk assessment in this modeling environment.

PROBLEM BACKGROUND

NASA's Aviation Safety Program is pursuing technologies to identify and improve hazardous situations within the national airspace system. Reducing safety hazards is a key requirement for continued growth in air traffic density that is necessary to meet continually increasing demand. Integrated safety analysis of day-to-day operations and the risks within those operations will provide an understanding of the AvSP portfolio that is not now available. If technology buyers understand the potential for risk reduction provided by technology implementation, they can develop business cases to evaluate tradeoffs among cost, performance, and safety. Ultimately, integrated system analyses that address safety, performance, and economics can provide useful information for choosing and supporting development programs. Figure 1-1 depicts the conceptual structure for such analyses and indicates the role of integrated safety analyses.
As Figure 1-1 shows, an integrated safety analysis is intended to provide useful data that can be applied to other analyses and to system design. An integrated safety analysis must be able to estimate the safety benefits from competing technologies for existing operations and investigate the safety implications of using new technologies to enable higher-capacity operations. Figure 1-2 depicts the methodology of an integrated safety analysis.

The reliability and interaction-response models are the two principal analytic components of the integrated safety analysis. These models are used to develop safety statistics necessary to determine whether the system meets acceptable safety levels. They also are necessary to conduct tradeoffs between safety levels and cost.
The basic algorithm for developing safety statistics is as follows:

\[ P_{\text{Accident}} = P_{\text{Failure}} \times (P_{\text{Accident} \mid \text{Failure}}) \]

\( P_{\text{Failure}} \) is the probability of a hardware or software failure, as estimated by the reliability model. \( P_{\text{Accident} \mid \text{Failure}} \) is the conditional probability of an accident given a failure, as estimated by the interaction-response model. We use Markov reliability models to estimate \( P_{\text{Failure}} \) and simulation to estimate \( P_{\text{Accident} \mid \text{Failure}} \).

A combination of reliability modeling plus simulation provides significant computational benefit over either method alone. Reliability models have difficulty addressing dynamic parameters such as pilot response and changing environment, whereas simulation of low-probability failures leads to an impractical number of computer runs. Using reliability models to estimate equipment failure rates and simulations to estimate the results when those failures occur adds dynamics to the reliability analysis and makes the simulation computationally tractable.

**SYNTHETIC VISION—DESCRIPTION**

Synthetic vision presents computer-generated views of the external environment to the pilot. The SV presentation is completely artificial. Typically it is based on a geographical and cultural database, supplemented by dynamic traffic information. For terrain, current experimental implementations of SV use global positioning satellite (GPS) position data to dynamically link the database to the aircraft's position and attitude. Supplemental sensors may be used to confirm the GPS position data and/or provide additional data (e.g., data about other aircraft, weather, or ground equipment). Airborne and ground traffic information may come from several sources, such as automatic dependent surveillance-broadcast (ADS-B) or cockpit display of traffic information (CDTI). SV systems can use head-up and head-down displays; the current concept focuses on a head-down display. Displays can include an artificial out-of-the-window view (in all directions) or a variety of symbolic and map presentations.

The primary purpose of SV is to improve safety by providing visual flight rule (VFR)-like situation awareness in instrument flight rule (IFR) conditions. The improved situation awareness provided by SV also can be used to improve operational performance. The performance goal of SV is to allow VFR-like operations in all IFR conditions down to Category IIIb. Such performance includes operations into runways that cannot use instrument landing systems because of terrain interference, independent approaches to closely spaced parallel runways, reduced in-trail separations between arriving aircraft, and low-visibility ground operations.

For analysis, SV performance can be defined by actual navigation performance (ANP) and traffic information. ANP is defined as the aircraft’s (and aircrew’s)
knowledge of its own position (plus speed and heading) with respect to the earth. Traffic information is defined as the aircraft's (and aircrew's) knowledge of the position, speed, and heading of other aircraft.

Alaska Airlines pioneered the use of navigational performance criteria for instrument flying, including development and approval of required navigational performance (RNP) IFR Category I approaches through mountain valleys to runways that have no instrument landing system (ILS) equipment. For those approaches, IFR landing is allowed when the actual navigational performance (ANP) meets or exceeds the RNP for the approach. Current RNPs for Category I approaches range from 0.15 to 0.30 nautical miles; lower RNPs allow lower decision heights, visibility, and ceilings. The Alaska Airlines RNP implementation establishes a series of waypoints that can be precisely flown on the basis of GPS and inertial reference data, coupled with the flight management system and autopilot. The Enhanced Ground Proximity Warning System (EGPWS), which provides a terrain display that is based on GPS data, provides supplemental information. Current ANP levels are achieved with nonaugmented GPS. Category IIIb operations, envisioned with SV, will require ANPs on the order of feet and consequently will require improved GPS accuracy provided by a local area augmentation system (LAAS).

**SYSTEM DESCRIPTION FOR RELIABILITY MODELING**

To estimate reliabilities we must specify SV hardware and software equipment, the number of redundant units, failure rates, recovery rates, and error detection coverage rates. The equipment includes items specifically identified with SV as well as items that are necessary for SV operations. Figures 1-3 and 1-4 are fault tree depictions of the equipment items and how they relate to support terrain avoidance and traffic avoidance respectively. Component definitions and reliability results are discussed in more detail in Chapter 2.
For simulation modeling, we need to define SVS performance parameter values for fully operational and degraded conditions. For all scenarios, we are concerned with the "own-aircraft" knowledge of its position, flight track, speed, and data.
latency. For scenarios that involve other traffic, we must add the own-aircraft knowledge of traffic aircraft position, heading, and velocity, with data latency. Terrain avoidance scenarios in this study are assumed to be at airports without radar surveillance, so the controller has no tactical traffic data. Traffic avoidance scenarios are assumed to be at airports that have air and surface radar surveillance, plus ADS-B traffic information; therefore, for such scenarios we specify the controller’s airborne and ground traffic data. Parameters considered in the simulation are as follows:

- **Terrain avoidance scenario:**
  - Own-aircraft knowledge of own-aircraft position, speed, track, data latency

- **Traffic avoidance scenario:**
  - Own-aircraft knowledge of own-aircraft position, speed, track, data latency
  - Own-aircraft knowledge of traffic position, speed, track, data latency
  - Controller knowledge of own-aircraft position, speed, track, data latency
  - Controller knowledge of traffic position, speed, track, data latency

- **Additional simulation parameters:**
  - Pilot and controller detection times
  - Pilot and controller communication times
  - Pilot and controller response times
  - Traffic density
  - Blunder geometry.

Most parameters are defined by a fixed bias and an uncertainty; others, such as ceiling, are defined by a single number, and some—such as blunder geometry—by extended definitions. Details of simulation parameters are discussed in Chapter 3.

Chapter 4 summarizes a subcontracted review of human factors modeling. Reliability data are discussed and documented in Appendix A. A brief discussion of Markov analysis and the input files for the reliability analysis are included in Appendix B. Finally, Appendix C contains miscellaneous references and data that are applicable to the simulations.
Chapter 2
Reliability Analysis

In this chapter, we document the assumptions, input parameters, and results of the Markov reliability analysis.

EQUIPMENT AND COMPONENTS

As discussed in Chapter 1, several systems in addition to the “synthetic vision” equipment are necessary for SV operation and must be included in the reliability analysis. Table 2-1 lists all equipment components and associated parameters. The components that make up equipment items are based on several sources, including a 1999 NASA report, Jane's Avionics, equipment brochures, technical reports, and engineering judgment. Although the architectures generally are representative and are appropriate for the purposes of this study, they are not defined to the level necessary for a detailed system-specific safety analysis. The model and methods are capable of such an analysis, however, if detailed equipment architectures are provided.

**FAILURE AND RECOVERY RATES**

The failure and recovery rates used in the analysis are from three sources. The 1999 NASA report is the basis for several of the components modeled in the analysis. The rates were based partly on government specifications and partly on engineering judgment. To substantiate the engineering judgment, we investigated two other sources. The first was the Air Force "DO41" peacetime maintenance database for the two years (eight quarters) ending in March 2000. The second was Jane's Avionics. Data from these sources are discussed in Appendix A. Although the new data added insight, there is still considerable engineering judgment included in the rate selection.

INDIVIDUAL EQUIPMENT DISCUSSIONS

GPS Satellites

The GPS system consists of 24 operational satellites, plus on-orbit spares. Three-dimensional navigation using GPS requires data from at least 4 satellites. The number of satellites that are within visual range at any one time varies from 4 to 13. Determination of the probability of successful GPS data acquisition is performed in three steps. First, the probability that 4-of-N satellites will be operational is estimated for the 10 cases where $N$ ranges from 4 to 13. Second, those probabilities are multiplied by the corresponding probabilities that 4 to 13 satellites will be in range. For example, the probability that 4-of-4 satellites will be working is multiplied by the probability that 4 satellites will be in range. Similarly, the probability that 4-of-5 satellites will be working is multiplied by the probability that 5 satellites will be in range, and so on through the probability of 4-of-13 working times 13 in range, for a total of 10 cases. Finally, the probabilities from the 10 cases are combined to determine the expected probability that at least 4 operational satellites will be acquired.

The probabilities that 4-of-N satellites will be working are estimated by using 10 different runs of a Markov model. The individual satellites are modeled as single units that can suffer hardware and software failures. Software failures are repairable, but hardware failures require satellite replacement. Failure and repair/replacement rates are listed in Table 2-1.

The probabilities that 4 to 13 satellites will be in range are taken from a 1997 NASA report. The in-range probabilities, shown in Table 2-2, are functions of latitude and elevation angle. For this analysis we used the 10 degree elevation angle values.

LAAS Range Sensor

The Local Area Augmentation System (LAAS) uses ground reference sensors located in the vicinity of the airport to measure local errors in GPS position data. The sensors’ basic functions are to determine their positions on the basis of GPS information and compare them to their known positions (based on surveys). The errors in the two positions are used to calculate corrections to GPS signals. At

---

3 Ibid.
least four reference stations must be operating to ensure the accuracy needed for IFR Category III operations.

The LAAS Range Sensor (LRS) is modeled as a GPS receiver system coupled to a communications transmitter system that transmits the sensor GPS position to the central LAAS ground facility. Figure 2-1 is a block diagram of the sensor. Multiple boxes in the block diagram indicate redundant equipment. For this study, we assume that all redundant equipment is cross-strapped and will automatically and instantaneously replace failed components.

![Figure 2-1. Block Diagram of LAAS Range Sensor](image)

We assume that six range sensors are deployed and require that four be operating. We run a Markov estimate for a single sensor and determine the probability that four of six sensors will be operating on the basis of a binomial distribution.

**LAAS Ground Facility**

The LAAS Ground Facility (LGF) receives GPS position data from the range sensors, calculates local errors in the GPS signals, and transmits correction data to aircraft and ground vehicles. LGF components are shown in Figure 2-2. For ease of analysis, the reliabilities of the processor and communications equipment are calculated separately.

![Figure 2-2. LAAS Ground Facility](image)

The processor model and associated failure and recovery rates are based on the analogous Wide Area Augmentation System (WAAS) processor. The processor is triply redundant, and hardware and software failures are modeled. Software failures are identified separately as loss of the basic correction signal and loss of the integrity signal needed to certify data accuracy. Although these failures can be used to identify degraded operating states, in the current analysis they are combined.

---

5 Kostiuk et al., *A System for Integrated Reliability and Safety Analysis*. 

NASA/CR—2001-211285 10
The LGF receiver/transmitter includes fully redundant antennas, receivers, and transmitters. Because it is located on the ground, its components are fully repairable. We assume that the LGF processor will be able to detect failures in ground facility signals and that there will be no undetected failures.

Airborne GPS Receiver

The components of the airborne GPS receiver are shown in Figure 2-3. The airborne components are not reparable during flight. The receiver and processor also may experience undetected failures. Coverage rates for undetected failures are based on values in the 1999 NASA report.6

![Figure 2-3. Airborne GPS Receiver](image)

SV Processor and Display

The SV hardware includes redundant processors and displays, as shown in Figure 2-4. The equipment is not reparable during flight. The processor and displays may experience undetected failures. For safety analysis purposes, we assume that these undetected failures could result in production and display of geographically biased images.

![Figure 2-4. Synthetic Vision Processor and Display](image)

CDTI Datalink

The CDTI datalink includes redundant ground transmitters and redundant airborne receivers, as shown in Figure 2-5. The ground transmitters are assumed to be repairable. Datalink failures are assumed to be fully detectable.

![Figure 2-5. CDTI Datalink](image)

---

6 Ibid.
CDTI and ADS-B (see below) provide traffic information to the aircrew. We assume that all information on ground traffic comes through CDTI; thus, if CDTI fails, the aircraft loses track of ground traffic.

**Automatic Dependent Surveillance-Broadcast**

The ADS-B components are based on the model in the 1999 NASA report. ADS-B components are shown in Figure 2-6.

*Figure 2–6. ADS-B*

![ ADS-B Diagram ](image)

None of the ADS-B equipment is reparable during flight, and all of it can experience undetected failures. We retain the ADS-B display in the model, however. ADS-B data may be displayed on the SV display.

**Flight Management System**

The FMS components shown in Figure 2-7 were based on the description of the Smith’s Industries FMS in the 1995 Jane’s Avionics.

*Figure 2–7. FMS*

![ FMS Diagram ](image)

The failure rate for the FMS inertial navigation system (INS) is set to zero in the analysis because the INS is assumed to be the same equipment used by the ADS-B and including failure here would be double-counting.

**Autopilot**

Autopilot components, shown in Figure 2-8, are based on the description of the Boeing 747 SPZ-1 autopilot in the 1995 Jane’s Avionics.
Airport Surface Detection Equipment

ASDE components, shown in Figure 2-9, are based on the primary radar model in the 1999 NASA report, with redundant processors added.7

The failure and repair rates for ASDE were taken from the model in the 1999 NASA report, which was based on airport surveillance radar. Two versions of ASDE are being fielded: the Ku-band ASDE-3 and the X-band ASDE-X. The reliabilities and repair times for these two versions are likely to be significantly different.

ADS-B Ground Surveillance Stations

The ADS-B ground surveillance stations components shown in Figure 2-10 are based on technical reports8 and industry information. The ADS-B ground sensors collect ADS-B transmissions from ground traffic and transmit them to a central processing facility. In this analysis, we assume that the central processing facility is the Airport Movement Area Safety System (AMASS).

---

7 Ibid.

8 For example, C. Evers, R. Cassell, and D. Lee. “Analysis of ADS-B, ASDE-3, and Multilateration Surveillance Performance—NASA Atlanta Demonstration.” presentation at 17th Digital Avionics Systems Conference. AIAA.
We assume that at least two of five stations must be operational to provide full airport coverage.

**Airport Movement Area Safety System Processor**

The AMASS processor, shown in Figure 2-11, is modeled as a triply redundant processor with cross-strapped, triply-redundant operating system software.

![Figure 2-11. AMASS Processor](image)

The AMASS processor integrates data from ASDE, ADS-B, and any other surface surveillance sensors; calculates trajectories; and generates warnings of predicted collisions.

**Common Avionics**

The common avionics category is a holding location for airborne equipment that may be needed but is not now considered essential. These equipment items are modeled as single components with nominal failure rates. The three items now included in the common avionics category are the aircraft weather radar, the traffic alert and collision warning system (TCAS), and the enhanced ground proximity warning system (EGPWS).

**RELIABILITY ANALYSIS**

We used Markov analysis tools developed by NASA to estimate reliability. We used the NASA Scaled Taylor Exponential Matrix (STEM) Markov analysis model to perform reliability calculations. We used the NASA Abstract Semi-Markov Specification Interface to the SURE Tool (ASSIST) to generate inputs for the model. The ASSIST code automates the generation of input files for three Markov analysis models: the semi-Markov unreliability range estimator (SURE), the Padé approximation with scaling (PAWS), and STEM.

Markov analysis and the specifics of the NASA models are well documented, and the mathematics underlying the SURE model are described elsewhere.

---

Appendix A contains a sample of model inputs and results, as well as the input files for all of the systems we analyzed.

**RELIABILITY SCENARIOS AND RESULTS**

We modeled two reliability analysis scenarios. The first is a terrain avoidance scenario. This scenario consists of an SV-supported IFR approach to a single-runway airport surrounded by high terrain (e.g., Juneau, AK). The terrain prevents the use of radar surveillance or instrument landing equipment. We assume that ground surveillance systems are not deployed at these airports. Traffic is not modeled in this scenario. The equipment content and failure results for this scenario are listed in Table 2-3.

Table 2-3 displays the failure results of all components included in the scenario, which produces the probability that all systems will be operating properly. These component results can be combined in other ways to determine the probabilities of specific hazardous conditions. For example, the most hazardous condition for the terrain scenario is an undetected bias in the terrain display. Such a bias could be caused by an undetected SV processor or display error \( P = 2.248E-8 \) that occurs only when no other detected failures have occurred \( 1-2.2E-3 \) or \( .9978 \), based on the assumption that known system failures would prompt the aircrew to execute an escape maneuver. The resulting probability would be \( 2.243E-8 \). Bias also could be caused by undetected erroneous GPS corrections, which we have not explicitly modeled.

The second scenario addresses traffic avoidance. In this case, the hazard is collision with other traffic—airborne and surface. The components of the system that are important in traffic avoidance include those from the terrain avoidance case as well as airborne and ground surveillance systems. Table 2-4 displays the equipment and the failures of all components in the traffic avoidance scenario.

---

11 The result is 0.9978 when the probabilities are summed without the SV processor and display.

</tbody>
</table>

As with the terrain scenario, determination of the probability of specific hazardous conditions requires additional thought. For example, a major hazard in the traffic case is own-aircraft loss of the ADS-B signal from the nearest traffic. This hazard could result from an undetected failure of the own-aircraft ADS-B receiver or the traffic aircraft’s ADS-B transmitter, again combined with the probability of no known escape-generating failures of other systems. A degraded state could exist if the own-aircraft was still receiving airport surveillance radar data on traffic from CDTI.

SUMMARY

The reliability analysis demonstrates the ability of the modeling approach to generate results that are adequate for integrated safety analysis of AvSP technologies. Individual component results provide insight into the benefits of redundancy and fault detection. The model is capable of accepting higher-fidelity system descriptions for safety analysis of specific hardware and software architectures. We note, however, that higher-fidelity descriptions are useful only if failure and repair data are available for the modeled items. Finally, we note that the reliability results can be readily manipulated to find the probabilities of specific failure combinations.
Chapter 3
Simulation Analysis

GENERAL MODEL APPROACH

The simulation model is used to determine the probability of a hazard or accident, given the existence of a system failure. Simulation also is the primary tool for investigating the impact of human response to equipment failures and the impact of human-initiated errors.

The simulation model is being developed under a parallel task. Unfortunately, it was not completed in time for this report. The analyses discussed in this chapter will be conducted when the model is complete; the results will be included in subsequent documentation.

SIMULATION STRUCTURE

Figure 3-1 outlines the programming structure of the simulation model. Here, as with any model, we must identify the best trade-off between model sophistication and realism versus complexity and processing time. The structure depicted is an object-oriented foundation architecture that is designed to allow “simple” initial models that can be replaced by more realistic algorithms as required.

Figure 3-1. Simulation Structure
For the current task, aircraft movements are defined by position coordinates and velocity vectors. Basic technology operational performance and failure conditions are modeled by distributions of position and velocity uncertainties. Turn radii and rates are based on simple aerodynamic formulae. Similarly, evasive maneuvers are simple climbing turns. In future model versions, the simple position and velocity definitions can be replaced by more sophisticated aircraft models maneuvers as the analysis demands. The current simple assumptions are considered adequate for assessing feasibility and analyzing the scenarios we are considering in this study.

SIMULATION PARAMETERS

Identification of simulation parameters presents interesting challenges. The national airspace system is as safe as it is because the potential for equipment failures is built into the specification of operating minimums. Determining safety improvements from new technologies under current operating conditions requires us to inject rare blunders into the simulation and see how the new technology improves the chance of survival. Similarly, investigating the safety of higher-capacity operations with new technology requires us to determine the probability of accident when blunders are injected and operational margins are reduced. In summary, we must identify the operating conditions of the current and new technologies, the nature of the blunder, and the expected response to the blunder. Finally, the probability of encountering a blunder must be included in the safety calculation:

\[ P_{\text{Accident}} = P_{\text{Failure}} \times (P_{\text{Accident | Failure}}) \times P_{\text{Blunder}} \]

Terrain Avoidance

The terrain avoidance scenario is concerned with controlled flight into terrain (CFIT). For terrain avoidance, we are concerned with simulating the approach of the aircraft through an obstacle-strewn path to a single runway airport. The scenario is modeled on the required navigation performance RNP approach to Juneau, AK, airport Runway 26. The approach path consists of a series of three-dimensionally defined waypoints that define a path between mountains to the runway. Neither radar surveillance nor radio landing aids are available. Figure 3-2 generally depicts the scenario.
The most hazardous failure of either the current RNP equipment or the SV system in the terrain avoidance scenario is an undetected bias (also known as map error) in the FMS/INS/GPS (for RNP) and database or the display (for SV). In both cases, the aircraft will deviate from the flight path until the aircraft is below the minimum decision altitude (MDA), at which time we assume the pilot will detect the error and attempt a recovery maneuver. The hazard obviously depends on the size and direction of the bias and height of the MDA. It also will depend on the response time of the pilot and the probability that the pilot will choose the correct escape maneuver. The improvement in safety from SV with LAAS will be a function of any reductions in crashes and the reduced probability of combined undetected failure of the FMS/INS/GPS and the SV equipment. Improved capacity safety will be modeled by determining the lowest MDA, where the SV system provides the current level of safety given an undetected bias.

The current scenario is fairly basic. The model is inherently capable of more sophistication. For example, if the EGPWS is independent of the SV, the probability that the aircrew will detect and respond to the bias can be modeled. The same modeling can be carried out if the weather radar is used to corroborate the registration of the SV display with actual terrain. Such analyses are left for the future.

The model requires means and uncertainties for the own-aircraft state parameters as a function of technology, for normal and blunder conditions. Table 3-1 shows these parameters for the terrain avoidance case.

**Table 3-1. Terrain Avoidance State Parameters**

</tr>
</tbody>
</table>
Finally, the simulation requires estimates of the probability that the aircrew will detect an error, the aircrew’s expected response time, the nature of the aircrew’s response, and the probability that the aircrew will choose the correct response. For the terrain avoidance case, we assume that the aircrew will detect the unsafe condition 2.0 seconds after reaching the MDA, respond in 1.0 second, and always respond with a climbing turn away from terrain.

FMS or SV drifts are basically caused by equipment failures; we need not include an additional blunder probability. The FMS and SV drifts can be modeled in more detail to improve the estimate of drift occurrence.¹

Traffic Avoidance Scenario

The traffic avoidance scenario is concerned with midair and runway collisions. The scenario is depicted in Figure 3-3; it includes own-aircraft and traffic approaches to parallel runways, as well as ground traffic on the own-aircraft runway. Full radar surveillance and ILS landing aids are assumed.

![Figure 3-3. Traffic Avoidance Scenario](image)

Two failures are considered in the traffic avoidance case. The first is an obstructed runway condition. The current-technology aircraft will be able to detect the threat visually when it reaches the MDA. The SV-equipped aircraft, supplemented by CDTI, will be able to detect the threat well out on the glideslope.

The second failure in the traffic avoidance scenario is a blunder toward the own-aircraft by the parallel traffic aircraft. This failure will be modeled with and without simultaneous loss of ADS-B data from the traffic aircraft. We further assume that the controller is able to detect the threat in the former case on the basis of surveillance radar information. In both cases, we assume that the own-aircraft can detect the intruder visually when they are both below the MDA. The probability of collision will be based on several factors, including the time required for the

¹ For further detail on sources of FMS drift, see “B737-300/400/500 FMC Position,” available at <http://194.78.76.133/linepilot/FMCPosition.html>.
controllers and aircrews to detect and respond to the threat, the height of the MDA, and the runway separation. The probability of a blunder is small. The Federal Aviation Administration’s Precision Runway Monitor Program Office estimates that the chance of a blunder is 1 in 25 million approaches.\(^2\)

The traffic scenario requires state variables for the own-aircraft’s knowledge of itself and the traffic, and the controller’s knowledge of airborne and ground traffic. Tables 3-2 and 3-3 contain the state variables.

</tbody>
</table>

The traffic scenarios are more complex than the terrain scenario but are still relatively basic. Future additions will include intrusion alerting algorithms, detailed aircraft-specific aerodynamics, and more complex traffic patterns.

**General Parameters**

In addition to the state variables, we also need to quantitatively define the general parameters mentioned in Chapter 1:

- Pilot and controller detection times
- Pilot and controller communication times
- Pilot and controller response times
- Traffic density:
  - *Detection times*: Pilot and controller detection times are assumed to be two cycles of the appropriate surveillance sensor. For ADS-B and ASDE, the update rate is 1 Hz, and the detection time is 2 seconds.

For the airport surveillance radar, the update rate is 0.25 Hz, and the detection time is 8 seconds.

- **Communication times:** Communication time applies to controller-to-pilot communications in cases in which the controller detects the threat. We use a communication time of 4 seconds.

- **Pilot and controller response time:** We assume a pilot response time of 2 seconds. This value is in accord with other analyses and with simulations. The controller is expected to respond immediately upon detection of a problem.

- **Traffic density:** Traffic is not modeled in the terrain scenario. For the current cases, only immediate-threat aircraft are included in the traffic scenario. The simulation structure is capable of full airport traffic modeling.

**SUMMARY**

We have chosen scenarios and parameters to demonstrate the feasibility of the estimating safety benefits of AvSP technologies. The success of the simulation effort is fully expected but, unfortunately, still unproven.

The foregoing parameters are based on interpolation from several sources. Appendix C contains a summary of references and parameter values.
Chapter 4
Human Factors Evaluation

This chapter summarizes the results of a subcontracted evaluation of the human factors modeling capacity of the LMI models. The analysis was conducted by Dr. Kevin Corker, San Jose State University.

There are three active functional elements in the LMI system. The first is system functionality, which can be described as a discrete state representation of the components. This element is addressed by Markov reliability analysis. The second element is the operational scenario, which provides the event driver for the simulation process. The third element is rules and procedures; in the current implementation, this element lacks an active agent—typically a human operator—to interpret, implement, and execute the rules and procedures. The role of an active agent (human element) can be filled by a submodel (or component model) that interacts with the simulation. Active-agent submodels can be identified for each active human element in the system to represent the response of the human component in the system. There can be different rules and procedures for each active agent. In addition to the diversity of rules and procedures, human performance also can be subject to processes that either degrade or improve a baseline performance.

The system architecture allows elaborated human operator performance models to contribute the output of the rules and procedures element of the system. The output of the human operator is not necessarily limited to failures or degradation. The human response to loads such as traffic density is to choose interpretations of rules to suit the required system state. The human operator may exhibit behavior that is more optimal if aiding systems are in place to improve the optimality of the system. The model requires a representation of the human operator that is consistent with the representation of the component systems and scenarios.

The standard representation of time lag is not sufficient to account for the parts of the perceptual and cognitive processes that will be affected by specific aiding technologies (e.g., enhanced SV). To accurately account for the impact of such technologies, there should be transition processes that represent the mechanisms of impact. In the SV case, there should be a modeled transition that represents the probability that the pilot will see potential obstructions. The effect of seeing something or not then changes the probability of one rule of behavior (e.g., if runway is clear, proceed with takeoff) as compared to another (if runway is occupied, reject takeoff). The change of rule probability would then affect the selection of behavior.

The probability of successful completion of an action also should be made responsive to conditions in the environment. For example, if the pilot encounters a
high task load because of traffic, weather, or communications, some reduction in
the probability of successful performance could be implemented. If there are
technologies to aid the performance of the output behavior, that technology—in
combination with human performance transitions—should show an increase in the
probability of successful performance. To summarize, the human performance
submodel should support mechanisms by which the presumed performance envi-
ronment can impact the output of that model.

Discrete event simulation human element submodels are consistent with the basic
LMI discrete event simulation architecture. Specifically, current research with
dynamically colored Petri net simulations could be applied to the LMI analysis.
The dynamically colored representation adds functions to a standard Petri net that
support the functionality required to represent improvements in safety (or capacity
enhancement) that are being evaluated. This method has been explored and devel-
oped by the Dutch Aerospace Research Laboratory (NLR) and applied to several
aeronautic scenarios. In collaboration with the NLR, San Jose State University
(under NASA safety program funding) is making the Man-machine Integration
Design and Analysis System (MIDAS) model a source of parameters to guide
transitions in the Petri net simulation. The MIDAS human performance models
respond to technological and procedural interventions. Discrete events generated
by the Petri net model as a result of MIDAS input potentially can be fed into the
standard risk assessment processing of the LMI simulation.

Figure 4-1 is a schematic of the MIDAS/Petri net interaction. The figure depicts
the situation in which a pilot alternates between informed and uninformed states
regarding traffic on the runway. Rules and procedures that are appropriate for
each state are contained in the human performance matrix (shown twice for clarity). The state circles and transition rectangles are elements of the Petri net. The
dot is a token that indicates that the pilot is in the “informed” state. Information
about the external world and the pilot’s internal human processes as modeled in
MIDAS can stimulate or inhibit transitions between the informed and uninformed
states, with corresponding changes in the pilot’s expected performance. In this
representation, the Petri net and MIDAS models interact to provide a process with
sufficient complexity to represent human performance with a link to the discrete
event simulation. In terms of safety analysis, the information processing element
of the models allows error and degradation of performance in the workings of the
MIDAS models. In addition, technologies that might improve awareness and/or
increase speed or accuracy will be represented through the action of MIDAS
models whose outputs modify the colored transitions in the Petri net representa-
tion. The output of the Petri net can then interact with the LMI safety/risk assess-
ment through the updated human performance matrix.

Reliability Data

As discussed in Chapter 2, the failure and recovery rates used in the analysis are from three sources. A 1999 NASA report is the basis for several of the components modeled in the analysis. The rates in this report were based partly on government specifications and partly on engineering judgment. To substantiate the engineering judgment, we investigated two additional sources. The first was the Air Force "DO41" peacetime maintenance database for the 2 years (8 quarters) ending in March 2000. The second was Jane's Avionics. Although the new data added insight, considerable engineering judgment remains in the rate selection.

The DO41 data are extracted from a database that LMI produced and maintains for the Air Force. The characteristics of the specific data used here include the following:

- **Data type**: Peacetime failure data
- **Data period**: March 1999 and previous 8 quarters (2 years)
- **Data records**: Total organizational and intermediate demand rates (TOIMDR) — unscheduled maintenance data for actual failures; failed to replicate cases are removed from the database
- **National Stock Number (NSN) categories searched**:
  - 5281: Radio and TV Communications—Airborne
  - 5826: Radio Navigation Equipment—Airborne
  - 6605: Navigation Instruments

The data were transferred to a Microsoft ACCESS database and searched to extract data on receivers, transmitters, inertial navigation/measurement systems, and so forth. The resulting tables were converted to Excel spreadsheets for analysis and display.

The equipment descriptions included in the DO41 data do not provide enough information to determine the assembly level of the equipment listed. The On-Line Federal Logistics Information System (Haystack service) was searched by NSN to gather more descriptive data. The Haystack data were added to the spreadsheets. Even with these data, questions remain. For future work, explicit information can

---

be found through research into the Air Force work unit codes (WUCs) and interviews with Air Force logistics personnel.

Several issues of *Jane’s Avionics* were searched to extract equipment descriptions any failure data. Supplemental data found in *Jane’s Avionics* were added to the spreadsheets.

Tables A-1 through A-3 are spreadsheets for receivers, transmitters, and inertial reference units. Study of these tables indicates the degree to which engineering judgment must be applied to the choice of rates for analysis.

Appendix B
Reliability Analysis Background and ASSIST Listings

This appendix briefly describes the Markov reliability analysis and documents the model input files.

The reliability analysis was performed with the NASA Scaled Taylor Exponential Matrix (STEM) Markov analysis model. The inputs for the model were generated by using the NASA Abstract Semi-Markov Specification Interface to the SURE Tool (ASSIST). The ASSIST code automates the generation of input files for three Markov analysis models: the semi-Markov unreliability range estimator (SURE), the Padé approximation with scaling (PAWS), and STEM.

Markov analysis and the specifics of the NASA models are well documented,¹ and the mathematics underlying the SURE model is described elsewhere.² Therefore, in this appendix we present only an outline of the method to illustrate the process.

**PROCESS OUTLINE AND EXAMPLE CASE**

The analysis is performed in four steps. The first step is definition of components to be analyzed and determination of appropriate failure, repair, and fault detection coverage rates. The second step is the writing of an ASSIST input file. The third step is running ASSIST to generate input files for the Markov analysis programs. Finally, a Markov analysis model is run to generate reliability results. The following paragraphs detail the process for a simple example: cockpit display of traffic information (CDTI).

In our analysis, CDTI is modeled as two ground transmitters and two airborne receivers. Ground transmitters can be repaired. We define a three-element state in which the first element is the number of operating transmitters, the second is the number of operating receivers, and the third is a failure flag that is 0 for operating conditions and 1 whenever all transmitters and/or all receivers have failed. Figure B-1 displays the potential states of the system.

---

Figure B-1. CDTI Markov Tree Diagram

Note that there are only 9 states and 18 transitions (arrows) in the tree. More complex systems can have hundreds of states and thousands of transitions, which become practically intractable without models such as ASSIST.

The purpose of the ASSIST model is to automatically generate the states and transitions, based on a description of system components as well as failure and recovery processes. By replacing numbers with algebraic variables, ASSIST can generate huge state/transition files, using very succinct code statements. The ASSIST coding for the CDTI is listed in Figure B-2.

Figure B-2. CDTI ASSIST Listing

(* Cockpit Display of Traffic Information (CDTI) ASSIST model *)
(* This model uses ADS_B receiver and transmitter parameters, *)
(* but assumes no uncovered hardware failures *)
(* Repair capability is added to the ground receiver and transmitter *)
(* Use of a common antenna with other equipment is assumed for both ground and air *)
(* There is only one CDTI per airport *)
LIST = 3; (* Needed for the .mod file *)

(* Numbers of each component *)
n_gtx = 2; (* Modulator and Transmitter *)
n_arx = 2; (* Receiver and Demodulator *)

(* other parameters *)
n_modes = 1; (* Number of system failure modes which will be differentiated in model *)

(* Failure rates -- per hour *)
l_gtx = 1e-4; (* Ground Transmitter *)
l_arx = 5.0e-5; (* Airborne Receiver *)

(* Recovery rates - per hour *)
R_gtx = 0.25; (* Ground Modulator and Transmitter repair, 4 hrs *)

(* State space definition: *)
(* m_gtx # Number of on-line Ground Transmitter channels *)
(* m_arx # Number of on-line Airborne Receiver channels *)
(* f_mode # Failure mode: 0 = operational, 1 = failed safe *)
Appendix B: Reliability Analysis Background and ASSIST Listings

SPACE = (n_gtx: 0..n_gtx, m_arx: 0..n_arx, f_mode: 0..n_modes);

(* Starting Info *)
START = (n_gtx, n_arx, 0);

(* Set up failure rates *)
(* Failure of Ground Transmitter channel *)
if (m_gtx > 1) TRANTO m_gtx = m_gtx - 1 by m_gtx * l_gtx;
if (m_gtx = 1) TRANTO m_gtx = m_gtx - 1, f_mode = 1 by m_gtx * l_gtx;

(* Failure of Airborne Receiver channel *)
if (m_arx > 1) TRANTO m_arx = m_arx - 1, by m_arx * l_arx;
if (m_arx = 1) TRANTO m_arx = m_arx - 1, f_mode = 1 by m_arx * l_arx;

(* Set up recovery rates *)
(* Recovery of Ground Transmitter *)
IF (m_gtx < n_gtx) AND (m_gtx > 0) TRANTO m_gtx = m_gtx + 1, BY (n_gtx - m_gtx) * R_gtx;
IF (m_gtx = 0) THEN
IF (m_arx < 0) THEN
TRANTO m_gtx = m_gtx + 1, f_mode = 0 BY R_gtx;
ELSE
TRANTO m_gtx = m_gtx + 1 BY R_gtx;
ENDIF;
ENDIF;

In this listing, the numbers of transmitters and receivers—n_gtx and n_arx—are variables (now set to 2, although they could be changed at will). The key to the ASSIST code is the transfer (TRANTO) statement, which controls the transfers among states:

if (m_gtx > 1) TRANTO m_gtx = m_gtx - 1 by m_gtx * l_gtx;

This statement says that for states in which more than one transmitter is operating, the assist code will generate a transfer to a state where one less transmitter is operating with a failure rate equal to the number of operating transmitters times the failure rate for transmitters (this rate assumes continuously operating spares). Thus, one statement can control all transitions that involve states with more than one operating transmitter. In the present case, we only have two transmitters; although the efficiency is not great, as the number and complexity of components increases, the power of the method becomes clear.

Running ASSIST generates a "mod" input file that can be used with any of the three Markov analysis models. The cdti.mod file listing is shown in Figure B-3.

Figure B–3. CDTI ASSIST Output File

LIST = 3;
N_GTX = 2;
N_ARX = 2;
N_MODES = 1;
L_GTX = 1E-4;
L_ARX = 5.0E-5;
R_GTX = 0.25;

1(* 2,2,0 *), 2(* 1,2,0 *) = 2*L_GTX;
1(* 2,2,0 *), 3(* 2,1,0 *) = 2*L_ARX;
2(* 1,2,0 *), 4(* 0,2,1 *) = 1*L_GTX;
2(* 1,2,0 *), 5(* 1,1,0 *) = 2*L_ARX;
2(* 1,2,0 *), 1(* 2,2,0 *) = (R_GTX-1)*R_GTX;
3(* 2,0,1 *), 5(* 1,1,0 *) = 2*L_GTX;
3(* 2,1,0 *), 6(* 2,0,1 *) = 1*L_ARX;

NASA/CR—2001-211285 33
Running the STEM model with the input file is straightforward. The command is `stem cdti.mod`. Because the analysis is time-dependent, we need to define the time period. For this case, we use 10 hours (based on the assumption that all equipment is operating at the beginning of the flight). The STEM command line statement is simply `time = 10`. The statement `run cdti.out` causes STEM to execute and store the results in a file `cdti.out`. The `cdti.out` file is shown in Figure B-4. Note that the `L` in the numbers represents the base 10 exponent.

Figure B-4. CDTI 10-Hour Output File

```
MODEL FILE = cdti.mod

*** START STATE ASSUMED TO BE 1

D-STATE  PROBABILITY  ACCURACY

TOTAL  0.0000000000000L+00  12 DIGITS

STATE  PROBABILITY

1  9.9826721154481L-01
2  7.3306059566549L-04
3  9.9853681994737L-04

9  5.6951696124529L-14
```

The analysis automatically checks for absorbing states that have no existing transitions. In the CDTI case, there are none of these $D$ or “death” states. We do have quasi-death conditions, however, because there is no repair of airborne receivers. The probability that we will find the system in states with failed receivers grows as time gets longer. Table B-1 and Figure B-5 display the results for 10 hours, 10,000 hours, and 100,000 hours.

</table>

Figure B-5. CDTI State Probabilities Versus Operating Time

As operating time increases, the population moves toward states with no operating receivers and—because the repair time for transmitters is rapid—toward states with two operating transmitters.

ASSIST LISTINGS

The remainder of this appendix contains ASSIST code listings for the systems analyzed. These listings can be copied, converted to text files, renamed with ".ast" extensions, and run.

GPS

(* Needed for the .mod file *)
LIST = 3;

(* Number of satellites - varies from 4 to 11 *)
INPUT REDUNDANT; (* command line entry: 4 to 13 *)
(* REDUNDANT = 4; *) (* alternate hard coded entry: 4 to 13 *)
(* Number of failure states *)
STATES = 2;

(* Failure Rates *)
FAIL1 = 4.51E-3;
FAIL2 = 4.39E-4;

(* Recovery rates *)
RECOVER1 = 1.96E-2;
RECOVER2 = 2.64E-2;

(* 1 means the repairs are done in parallel, 0 means in series *)
PARALLEL = 0;

(* Starting Info *)
SPACE = (WORKING: 0..REDUNDANT, ITEM : ARRAY[1..STATES] OF 0..REDUNDANT);
START = (REDUNDANT, STATES OF 0);

(* Set up the failure rates *)
IF (WORKING > 0) THEN
FOR I = 1,STATES
   TRANTO WORKING = WORKING - i, ITEM[I] = ITEM[I] + 1 BY WORKING * FAIL^I;
ENDFOR;
ENDIF;
FOR I = 1,STATES
   IF (ITEM[I] > 0) THEN
      IF (PARALLEL = i) THEN
         TRANTO WORKING = WORKING + I, ITEM[I] = ITEM[I] - 1 BY ITEM[I]*RECOVER^I;
      ELSE
         TRANTO WORKING = WORKING + I, ITEM[I] = ITEM[I] - 1 BY RECOVER^I;
      ENDIF;
   ENDIF;
ENDFOR;

This version of GPS requires a command line entry for the number of satellites.
STEM automatically provides a prompt.

LAAS Ground Reference Station

Appendix C
Miscellaneous References

The appendix lists information that was collected during this study on parameters related to the simulation. Accurate values of aircraft performance and air and ground surveillance parameters are required for valid simulation of the terminal airspace and new technologies. Many of the required parameters are for systems that are still in development—such as LAAS—or for systems for which definitive performance is hard to measure, such as ASDE. The information in this appendix provides data for parameter selection and insight into the quality of the data.

AIRBORNE PERFORMANCE

- **WAAS testing results:** 3 m horizontal, 4.5 m. vertical
- **LAAS test vehicle:** 0.2 m “accuracy” in NAV CANADA Cessna 182.

- <1 m CEP DGPS RTCM-104
- <3 m CEP WAAS DGPS
- <16 m CEP GPS w/o SEP
- <40 m CEP GPS w/SEP

**Update rates:** 1, 2, 5, and 10 Hz.

- **2-D accuracy, nmi (95 percent confidence)**
  - Terminal: 0.124
  - Nonprecision Approach: 0.056
- **GPS position fixing error**
  - Equipment without GPS: 1.7
  - Equipment with GPS: 0.3
- Single VOR/DME 0.5

R. A Swider, R. Braff, J. Warburton, and V. Wullschleger, *Local Area Augmentation System (LAAS) Update*, FAA Report, no date, paragraph 2.2

Required LAAS vertical position accuracy:

- CAT I 4.0 m
- CAT II 2.5 m
- CAT III 2.5 m

but integrity requirements will result in 0.6–1.0 m need for CAT III.

**GROUND SURVEILLANCE**

ASDE/AMASS: *Speed accuracy*: 1.9 kt mean, 1.6 kt standard deviation

- *Heading accuracy*: 4.7 deg. mean, 4.3 deg. standard deviation
- *Position accuracy*: 3.5 m mean, 2.0 m standard deviation
- (95 percent position): ± 6.4 m.

ADS-B: *Total horizontal position error*: mean = 0.7 m, 1 σ = 0.4 m,

- (95 percent position) = ± 1.42 m.

Multilateration: *Total horizontal position error*: mean = 3.1–8.5 m, 1 σ = 2.1–4.8 m,

- (95 percent position) = ± 7.4 – 15.3 m.

Appendix C: Miscellaneous References

ADS-B mean position lagged ASDE as much as 83 ft for accelerating targets because of latency. One Mode-S ADS-B transponder had a process time of 220 msec and a total response time of up to 1.22 sec.

This brochure includes a description of a multilateration ground sensor.

CONTROLLER AND PILOT RESPONSE

This report describes simulation and analysis of independent approaches to closely spaced runways during use of a precision runway monitor (PRM) radar. The authors develop a sophisticated and elegant alerting logic. The report cites the following FAA information from sources that are referenced but unavailable.

Based on “several experimental measurements:”

- “One or two radar updates may occur before the controller decides that an alert is necessary.”
- “The time delay between Not Transgression Zone penetration and controller response of over 5 seconds in over 20 percent of the time.”
- “Recordings made of terminal area communications indicate that the controller will be able to transmit without delay [to clear the channel] with a probability of 0.93, but the maximum wait may be over 8 seconds.”
- “A study by the Precision Runway Monitor Program Office estimates that only one blunder will occur during every 25 million approaches.” The same study estimates that the PRM allows only 1 accident in every 250 worst-case blunders.
State variables in the study, based on Rockwell-Collins simulation data and use of DGPS, were assumed to have 0-centered Gaussian distributions standard deviations:

<table>
<thead>
<tr>
<th>State measurement</th>
<th>Standard deviation</th>
</tr>
</thead>
<tbody>
<tr>
<td>x (relative lateral position)</td>
<td>$\sigma_x = 35$ ft</td>
</tr>
<tr>
<td>y (relative longitudinal position)</td>
<td>$\sigma_y = 35$ ft</td>
</tr>
<tr>
<td>$\psi$ (heading)</td>
<td>$\sigma_\psi = 2.5^\circ$</td>
</tr>
<tr>
<td>$\phi$ (bank angle)</td>
<td>$\sigma_\phi = 5.0^\circ$</td>
</tr>
</tbody>
</table>

This report also describes modeling and analysis of independent approaches to closely spaced runways, using PRM. The report includes distributions of controller and pilot response times. The controller is multimodal, with peaks at the PRM scans. The pilot response is assumed to have a Rayleigh distribution with a sigma of 5 seconds. The convolution of the two is roughly Rayleigh, with a range of 1–20 sec and a broad peak at 7–8 sec.

A Synthetic Vision Preliminary Integrated Safety Analysis

Robert Hemm and Scott Houser

Logistics Management Institute
2000 Corporate Ridge
McLean, Virginia 22102-7805

National Aeronautics and Space Administration
Washington, DC 20546-0001

Prepared pursuant to Contract NAS2-14361. The views expressed here are those of the Logistics Management Institute at the time of issue but not necessarily those of the National Aeronautics and Space Administration. Permission to quote or reproduce any part except for Government purposes must be obtained from the Logistics Management Institute. This report prepared for and managed by Glenn Research Center as a task of Ames Research Center Contract NAS2-14361. Project Manager, Mary Reveley, Aeronautics Directorate, NASA Glenn Research Center, organization code 2400, 216--433-6511.

This report documents efforts to analyze a sample of aviation safety programs, using the LMI-developed integrated safety analysis tool to determine the change in system risk resulting from Aviation Safety Program (AvSP) technology implementation. Specifically, we have worked to modify existing system safety tools to address the safety impact of synthetic vision (SV) technology. Safety metrics include reliability, availability, and resultant hazard. This analysis of SV technology is intended to be part of a larger effort to develop a model that is capable of "providing further support to the product design and development team as additional information becomes available." The reliability analysis portion of the effort is complete and is fully documented in this report. The simulation analysis is still underway; it will be documented in a subsequent report. The specific goal of this effort is to apply the integrated safety analysis to SV technology. This report also contains a brief discussion of data necessary to expand the human performance capability of the model, as well as a discussion of human behavior and its implications for system risk assessment in this modeling environment.
