The theory of stochastic transcription termination based on free-energy competition\(^1\) requires two or more reaction rates to be delicately balanced over a wide range of physical conditions. A large body of work on glasses and large molecules suggests that this should be impossible in such a large system in the absence of a new organizing principle of matter. We review the experimental literature of termination and find no evidence for such a principle but many troubling inconsistencies, most notably anomalous memory effects. These suggest that termination has a deterministic component and may conceivably be not stochastic at all. We find that a key experiment by Wilson and von Hippel\(^2\) allegedly refuting deterministic termination was an incorrectly analyzed regulatory effect of Mg\(^{2+}\) binding.

I. INTRODUCTION

The branching ratio of the termination process in gene transcription is balanced. In the case most thoroughly studied, \(\rho\)-independent termination in procaryotes, conventional gel experiments performed \textit{in vitro} find a fraction \(P\) of elongating RNA polymerase reading through the termination sequence with \(|\ln(1/P - 1)| < 4\) essentially always, even though \(P\) is different for different terminators and can be made to exhibit order-1 changes by perturbing the environment. This effect is astonishing from the standpoint of microscopic physics because a stochastic decision to read through or not requires a competition of transition rates - quantities of inverse time - that must be nearly equal for the branching to be balanced. RNA polymerase, however, is more the size of a glass simulation than a small molecule and thus possesses a broad spectrum of natural time scales spanning many decades. Without some physical reason for a particular scale to be preferred, rate competition ought to have been severely unbalanced, meaning that one event occurs essentially always and the other never. Balanced branching in termination has been implicated in transcription regulation in a few cases,\(^3\) but its broader significance, especially its robustness, is still a mystery.

In this paper we examine the experimental facts relevant to the physical nature of termination with the goal of determining what, if any, principle selects the time scale for stochastic rate balance. Our conclusion is both surprising and unsettling. We find no evidence for such a principle, but glaring weaknesses in the case for stochasticity and a large body of unexplained experimental results pointing to a termination decision that is partially deterministic. In light of the inaccessability of systems this large to ab-initio computation we conclude that transcription termination is a fundamentally unsolved problem in mesoscopic physics and an ideal target for the emerging techniques of nanoscience.

II. TERMINATION EFFICIENCY

The simplest termination sequences are the \(\rho\)-independent terminators of procaryotes, which are capable of causing polymerase to terminate \textit{in vitro} in the absence of the \(\rho\) protein factor. A representative sampling of these is reproduced in Table I. This differs from lists that have appeared in the literature before\(^4,5\) by having been rechecked against the fully-sequenced genome\(^6\) and expunged of “theoretical” terminators identified only by computer search. They conform for the most part to the motif of a palindrome of typically 10 base pairs followed by a short poly-T stretch, although there is tremendous variety in the length and composition of the palindrome, variation in the length of the poly-T stretch, and occasional extension of the palindrome to include the poly-T stretch. This enormous variability contrasts with the simplicity of stop codons, which terminate protein synthesis by ribosomes and have no other function.

\(\rho\)-independent terminators are characterized by “efficiencies”, i.e., the fraction of assayed transcripts that terminate. These rarely take on extreme values close to 0 or 1 when measured \textit{in vitro}. In cases where a measurement \textit{in vivo} exists as well the latter is usually larger\(^7\) and is occasionally unmeasurably close to 1. Balanced termination efficiency is commonly observed \textit{in vitro} as well, however. Table II shows results from a particularly careful study\(^7\) \textit{in vitro} in which termination probabilities in \textit{E. coli} for wild-type terminators, mutant terminators, phage terminators,\(^8\) and terminators from \textit{S. Boydii} were measured under identical conditions. Despite the great variety of these sequences the termination efficiency runs only
lowed by 3 mutants, 3 phage terminators, and one from Boydii.

The first standard direction and are aligned at the poly-T stretch. The palindrome is underlined. The beginning and end of the selected sequences are termination zones.

TABLE I. icer-independent terminators in E. coli taken primarily from Brendel et al. These are oriented in the reading direction and are aligned at the poly-T stretch. The palindrome is underlined. The beginning and end of the selected sequences have no absolute meaning but simply follow the convention of d'Aubenton et al. The address identifies the location in the standard E. coli genome of the left-most nucleotide in the table.

TABLE II. Termination efficiencies measured in vitro. The first 3 terminators are native to E. coli. These are followed by 3 mutants, 3 phage terminators, and one from S. Boydii. Far-right underlined sequences are termination zones.

TABLE III. Termination efficiencies for modified versions of the phage T terminator. From 2% to 88%. Many other researchers report similar values for terminators in E. coli and other bacteria, including artificially altered terminators.
III. LARGE MOLECULES AND GLASSES

Large systems are qualitatively different from small ones. The specific heat of all non-crystalline matter in macroscopic quantities - including biological matter - is proportional to T at low temperatures. This behavior is fundamentally incompatible with the linear vibration of the atoms around sites, and is caused by collective quantum tunneling of atoms between energetically equivalent "frustrated" configurations. It contrasts sharply with the exponential behavior of crystals with small unit cells. Glasses also exhibit stretched-exponential time dependence in response to perturbations, i.e., of the form \( \exp(-At^\beta) \) with \( \beta < 1 \), indicating a broad spectrum of decay rates rather than just one. They also exhibit memory effects, such as "remanence" in spin glasses or the well-known failure of ordinary silica to crystallize without annealing. This behavior is universal and robust. All non-crystalline macroscopic matter exhibits hysteresis, meta-stability, a broad spectrum of relaxation times, and memory.

How large a system must be before it can exhibit such behavior is not known, as the relevant experiments are difficult to perform except on macroscopic samples, but there are many indications that even medium-sized proteins have glass-like properties. Crystals of myoglobin, a protein with a molecular weight of only 17,000, have linear specific heats at low temperatures and exhibit stretched-exponential response to photodissociation pulses. Denatured proteins refold on a variety of time scales ranging from nanoseconds to seconds, and amino acids sequences chosen at random will not fold at all. Permanent misfolding of proteins with molecular weights of only 30,000 has been implicated in prion diseases. Many enzymes exhibit hysteresis in their catalytic rates. The activity of cholesterol oxidase of Brevibacterium sp., a protein with molecular weight 53,000, was recently shown by fluorescence correlation techniques to have a memory effect persisting about 1 second under normal conditions at room temperature. Other notable examples include wheat germ hexokinase (mol. wt. 50,000) with a half-life of 2 minutes, liver glucokinase (mol. wt. 52,000) at 1 minute, and yeast hexokinase (mol. wt. 50,000) at 1-2 minutes. Thus RNA polymerase complexes, which have a molecular weight of 379,000 and are comparable in size to the largest computer simulations of glasses ever performed, are good candidates for systems that exhibit glassy behavior.

Glassiness in enzymes is not always easy to observe. The mnemonic effect in yeast hexokinase occurs when it is preincubated with MgATP and free Mg\(^{2+}\) and the reaction is started with glucose, or preincubated with glucose and free Mg\(^{2+}\) and started with MgATP, but not if the enzyme is preincubated with glucose and metal-free ATP and then started with Mg\(^{2+}\). Mnemonic behavior can be destroyed by "desensitizing" the enzyme with contaminants. Time scales can depend on enzyme, substrate, product, activator and effector ligand concentrations as well as pH, buffers, and temperature. Before hysteresis and memory effects were recognized, early investigators generally adjusted such reaction conditions as well as pH, buffers, and temperature.23,29,30 Before hysteresis and memory effects were recognized, early investigators generally adjusted such reaction conditions until the "improper" behavior was eliminated.

IV. POLYMERASE STATES

While the size of RNA polymerase makes it plausible to expect glassy behavior on purely theoretical grounds, several direct lines of evidence indicate that the enzyme exhibits a spectrum of multiconformational, mnemonic and hysteretic behavior:

1. Polymerase has a catalytic mode distinct from RNA synthesis, as it can cleave the RNA transcript through hydrolysis (rather than pyrophosphorylysis, the reverse reaction of RNA synthesis), with the cleavage reaction requiring Mg\(^{2+}\) and being template-dependent, changing the polymerase footprint size, and stimulated either by GreA and GreB proteins or by high pH (8.5-10.0). The last effect was discovered serendipitously, going unobserved for decades because assay conditions were being optimized to maximize elongation rates, which occur at lower pH values (7.8-8.2). The poly-A effect is also observed with RNA transcripts and ribonuclease digestion.

2. RNA polymerase mobilities in non-denaturing electrophoresis gels show significant and discontinuous variance while bearing nearly identical transcripts or identical length transcripts with different sequences. These mobility variances are still observed if the RNA transcript is first removed by ribonuclease digestion.
3. RNA polymerase ternary complexes vary greatly in their stability and mode of binding to DNA (ionic or non-ionic) in a template-dependent manner. Some complexes are stable against very high salt concentrations ([K+] = 1 M), while others (specifically those proximal to an upstream palindrome sequence) are salt-sensitive (completely dissociating in concentrations as low as 20 mM K+). However, the salt-sensitive complexes are stabilized by millimolar concentrations of Mg2+.40

4. The size of the RNA polymerase footprint on the DNA template measured by ribonuclease digestion is significantly altered even at adjacent template positions, suggesting that the enzyme assumes different conformations during elongation.41

5. Guanosine tetraphosphate (ppGpp) inhibits the rate of elongation on natural DNA templates but not on synthetic dinucleotide polymer templates, and does not inhibit elongation by competing with NTP binding, but by enhancing pausing. It must therefore bind to polymerase and modify its behavior at an unrelated regulatory site in an allosteric manner, rather than interfering with the substrate binding site.42

6. The stability of a stalled elongation complex depends on whether the polymerase arrives at the stall site via synthesis or pyrophosphorylation.43

7. Termination efficiencies are affected by transcribed upstream sequences and untranscribed downstream sequences adjacent to the terminator.44

8. Stalling elongating polymerase complexes (via nucleotide starvation) and then restarting them by nucleotide addition perturbs pausing patterns 50-60 base pairs downstream.45

9. An elongating polymerase’s Michaelis constants $K_S$ for NTPs vary over 500-fold for different DNA template positions,46 and for different templates,47 although these effects are not observed for synthetic dinucleotide polymer templates.48

10. The rate of misincorporation at a single site for which the correct NTP is absent is significantly different before and after isolation of ternary complexes.49

11. Stalled polymerase gradually “arrests” (i.e., is incapable of elongating when supplied with NTPs), with the approximate half-time for arrest estimated at 5 minutes40 and 10 minutes49 for different DNA templates. The polymerase can continue elongating if reactivated by pyrophosphorylation.40

12. Even after undergoing arrest, crosslinking experiments show that the internal structure of polymerase gradually changes over the course of the next hour.49

13. Observations of single elongating RNA polymerase molecules show that it has two elongation modes with different intrinsic transcription rates and propensities to pause and arrest.80

The possibility of metastability - through shape memory or the conditional attachment of factors - is directly relevant to the rate-balance conundrum because it provides a simple alternative to balanced stochastic branching that requires no physical miracles. If, for example, the polymerase possessed a small number of metastable configurational states and terminated deterministically depending on which state it was in, then balanced branching would be a simple, automatic consequence of scrambling the state populations.

V. THERMAL ACTIVATION

The idea that polymerase memory is potentially relevant to expression regulation is not new.47 It is implicit in the work of Goliger et al81 and Telesnitsky and Chamberlin44 and even explicitly speculated by the latter in print. However, because of the experimental evidence supporting the stochastic model of termination1 and the widespread belief - unjustified, in our view - that proteins equilibrate rapidly, this suggestion generated little enthusiasm. A key experiment supporting the stochastic model by Wilson and von Hippel2 is both historically important and typical, so it is appropriate that we consider it carefully.

Wilson and von Hippel promoted and stalled RNA polymerase 8 base pairs upstream of the tR2 terminator hairpin of phage λ in vitro, thermally equilibrated at temperature $T$, and then launched it forward by adding NTP. The results are reproduced in Fig. 1a. Termination occurred at sites 7, 8, and 9 base pairs downstream of the beginning of the poly-T stretch (cf. Table II) with probabilities $P_7 = N_7/N$, $P_8 = N_8/N$ and $P_9 = N_9/N$. The data were originally reported as a semilogarithmic plot of $1/P - 1$ against temperature, where $P_i = N_i/N$, $P_6 = N_6/(N - N_7)$ and $P_9 = N_9/(N - N_7 - N_8)$. They concluded that all three branching probabilities $P$ were thermally activated and had distinctly different activation energies. However, it is clear from Fig. 1a that this conclusion is false. The three probabilities $P$ are essentially the same function and are well characterized by the sum $P = P_7 + P_8 + P_9$, also plotted in Fig. 1a. This is shown more explicitly in Fig. 1b, where the ratios $P_7/P$, $P_8/P$, and $P_9/P$ are plotted against temperature. The flatness of these curves shows that the branching ratios among the three sites are essentially constant and independent of temperature within the error bars of the experiment. Note that these fractions are also all of order 1. Thus the alleged spread in activation energies was an artifact of the plotting procedure.

Let us now consider the temperature dependence. It may be seen from Fig. 1a that $P$ saturates to 1 at 80 °C, the temperature at which Wilson and von Hippel
FIG. 1. a) Temperature dependence of termination probability \( P \) for phage \( \lambda \) terminator tR2 reported by Wilson and von Hippel.\(^2\) +, \( \Box \), and \( \times \) denote the probabilities to terminate 7, 8, and 9 nucleotides downstream from the beginning of the poly-T stretch. The sum is shown as \( \Diamond \). b) +, \( \Box \), and \( \times \) above divided by \( \Diamond \) to make a branching fraction \( f \). c) Comparison of ionization model Eq. (1) with \( \Diamond \) from a). The ionization energy has been fit to \( \epsilon_0 = 0.7 \text{eV} \) (16 kcal/mole) and the quantity \( n/M^{3/2} \) adjusted to make the curves match at 30 °C. d) Prediction of Eqn. (1) for dependence on Mg\(^{2+}\) concentration compared with data of Reynolds et al.\(^7\)report that the polymerase “will not elongate”, i.e., has stopped working properly. This suggests that the effect has something to do with the overall mechanical integrity of the enzyme rather than the termination process alone. Guided by this observation we note that the activated behavior identified by Wilson and von Hippel is actually the formula for conventional monomolecular chemical equilibrium. The probability for a particle of mass \( M \) with a binding energy of \( E_0 \) to be ionized off the polymerase is

\[
P = \frac{1}{1 + Z e^{E_0/k_B T} n^{3/2}} \lambda_{th}^3
\]

(1)

where \( n \) is the concentration of this component and \( Z \) is the change to the internal partition function that results from binding. If one makes the approximation that \( \lambda_{th} \) is a slowly-varying function of temperature and can thus be taken to be constant then this reduces to the formula with which Wilson and von Hippel fit their data.\(^2\)

That it works may be seen in Fig. 1c, where we plot the total termination probability from experiment against Eq. (1) with \( E_0 = 0.7 \text{eV} \) and \( Z \) adjusted to match experiment at \( T = 30 \) °C. Thus, reinterpreting this effect as an ionization equilibrium, we may account for the high-temperature intercept and weak temperature dependence seen in Fig. 1b in the following way: In addition to the ionization state the polymerase possesses an internal configurational memory with a number of states of order 10. These code for termination at sites 7, 8 or 9. In the equilibrium step, the polymerase molecules come to thermal equilibrium and a fraction \( P \) of them become ionized. All of these terminate at one of the three sites when launched. The rest read through.

A candidate for the ionizable component is an Mg\(^{2+}\) ion. In their studies of the effects of ion concentrations on termination efficiency, Reynolds et al.\(^7\) discovered that Mg\(^{2+}\) has the strange and unique effect of increasing termination efficiency to 100% for all terminators studied when reduced below 1 mM. The Mg\(^{2+}\) concentration in the experiments shown in Fig. 1d was 10 mM.\(^2\) Extrapolating at \( T = 30 \) °C using Eq. (1) we obtain, with no adjustable parameters, the fit to the [MgCl\(_2\)] dependence found by Reynolds et al.\(^7\) shown in Fig. 1d. The quality of this fit suggests that Mg\(^{2+}\) has a special function in regulating transcription, and that the temperature dependence in Fig. 1a is simply a thermal binding relation for this ion. This is corroborated by the recent structural studies of Zhang et al.,\(^5\) who report that polymerase crystallized out of 10 mM solution of MgCl\(_2\) has a Mg\(^{2+}\) ion bound at what appears to be the catalytic site of the enzyme.

There is evidence for more termination channels other than the ionization of Mg\(^{2+}\). In Fig. 2 we reproduce results of Reynolds et al.\(^7\) showing that terminator efficiencies tend to saturate at large Mg\(^{2+}\) concentration to values other than zero. The saturation values are balanced, and there is an evident tendency of them to cluster. Both effects are consistent with the polymerase executing an instruction at the terminator to read through conditionally, even when the ionizable component is bound, if its memory is appropriately set. There is obviously not.
ENough data here to draw such a conclusion, however. We note that Reynolds et al.7 also found order-1 effects on the termination efficiency from Cl– and K+, although with the opposite sign. The function of these ions is not yet known.

VI. ANTITERMINATION

What experiments can detect internal memory? In general, one would look for cases in which polymerase acts differently under apparently identical conditions, suggesting an internal control mechanism of some kind. Such thinking motivates the following hypothetical experiment: one constructs a template with promoter P followed by two identical terminators and flanking DNA sequences in succession. If termination is stochastic, then the branching ratio at T2 will be the same as that at T1. If termination is deterministic and hysteretic, then the branching ratios will be different, depending on details. A passive termination at T1 would result in no termination at T2, since the polymerase that reads through has been "polarized", i.e., selected for the memory setting that codes for read-through. An active termination at T1 would reprogram the memory there and cause a branching ratio at T2 different from that of T1 would reprogram the memory there and cause a branching ratio at T2 different from that of T1.

Branching ratios will be different, depending on details. If termination is deterministic and hysteretic, then the branching ratio at T2 will be the same as that at T1.

There are, top to bottom at the right edge, RNA I, T7Te, rrib T1, trp a L125, trp a, trb, T9Te, P14, tonB t, and trp a L153.

FIG. 2. Termination efficiency as function of [MgCl2] for 10 terminators, as reported by Reynolds et al. The terminators are, top to bottom at the right edge, RNA I, T7Te, rrib T1, trp a L125, trp a, trb, T9Te, P14, tonB t, and trp a L153.

It is not true generally. 44 There is also evidence that polymerase to form a loop.55 There is also evidence that it is not true generally. 44

In 1989 Telesnitsky and Chamberlin44 reported memory effects associated with the lac antiterminator found just downstream of the P_{lac} promoter in E. coli. Their key result is reproduced in Table V. Insertion of lac 353 nucleotides upstream of the terminator makes different order-1 modifications to the termination efficiencies of T7Te phage and trp a. The antiterminator contains a palindrome, and the antitermination effect is sensitive to modifications of the downstream 15-base-pair sequence. 3 copies of T7Te placed in tandem downstream of lac showed that the antitermination effect is partially remembered through multiple terminators; the efficiencies were 44%, 60%, and 90%, but without the antiterminator they were 90%, >90%, and >90%.

In another experiment in vitro reported in 1989, Goliger et al.51 found that the E. coli terminator rpoC t and phage terminators oop t and t92 were strongly antiterminated by a sequence they constructed accidentally. Their key result is reproduced in Table VI. A phage 82 promoter was fused onto a sequence containing either rpoC t alone or oop t
and \( \text{rpoC} \) t in tandem using the EcoRI linker sequence GGAATTC. This resulted in unexpected antitermination in \textit{vitro} of both terminators, but of different sizes that depended sensitively on the insertion point. The read-through effects in the tandem experiments were unfortunately poorly documented. One can see from Table V that the phage terminator responded more strongly in this experiment than did \( \text{rpoC} \) t. However, the reverse was the case in another experiment in which the antiterminator was a portion of the 6S RNA gene downstream of a phage \( \lambda \) pR promoter, and in which factor \( \text{NusA} \) was present. As a control, this latter experiment was rerun with the phage terminator \( t_{\text{g2}} \), which terminated at greater than 98% in all cases, seemingly immune to the manuscript.

King \textit{et al} \textsuperscript{52} reported in 1996 that the \( \text{putL} \) and \( \text{putR} \) antitermination sequences of the Hong Kong phage HK022,\textsuperscript{56} shown in Table VII, caused downstream readthrough of a triple terminator consisting of \( tR' \) from phage \( \lambda \) followed by the strong \( E. \text{coli} \) ribosome operon terminators \( \text{rrnB} t_{1} \) and \( \text{rrnB} t_{2} \). This effect was sensitive to the choice of promoter. When \( \text{putL} \) was inserted between the \( \text{Ptac} \) promoter and the triple terminator 284 nucleotides downstream and studied \textit{in vivo} the termination probability was 50%. Substituting the phage \( \lambda \) P\textsubscript{L} promoter for \( \text{Ptac} \) under the same conditions resulted in complete readthrough (though with wide error bars). When this experiment was repeated \textit{in vitro} the antitermination effect was found to be smaller and to persist through all three terminators. The read-through probabilities at \( tR' \) were 34% and 31% for promotion by P\textsubscript{L} and \( \text{Ptac} \), respectively, but 57% and 27% for \( \text{rrnB} t_{1} \) and 76% and 40% for \( \text{rrnB} t_{2} \). This result is incompatible with statistical termination, for both the antitermination effect itself and the changes resulting from switching promoters are order-1 effects that do not add. They also reported that reduced Mg\textsuperscript{2+} concentration destroys the antitermination effect.

### VII. CONCLUSION

In summary we find that the theory of stochastic termination, which requires natural selection to engineer a physical miracle of balanced rates, is flawed, but that there is ample evidence of a sophisticated and as-yet poorly understood regulatory system in RNA polymerase involving hysteresis, metastability, and long-term configurational memory, all robust phenomena in inanimate matter. On this basis we predict that branching ratios of identical terminators in series will differ by order-1 amounts very generally - specifically in the absence of looping. We propose that the confusion surrounding the existence of polymerase memory is symptomatic of the larger problem that measurement of physical activity on the length and time scales appropriate to life has thus far been impossible, and that overcoming this problem should be one of the high-priority goals of modern nanoscience.

This work was supported primarily by NASA Collaborative Agreement NCC 2-794. SL would like to acknowledge informative discussions with Brian Ring. RBL wishes to express special thanks to the organizers of the Keystone conferences, particularly R. Craig, for encouraging interdisciplinary science. We also wish to thank the Institute for Complex Adaptive Matter at Los Alamos, the Brown-Botstein group at Stanford for numerous stimulating discussions, and H. Frauenfelder, J. W. Roberts, D. Botstein and M. J. Chamberlin for a critical reading of the manuscript.
