The LIULIN-3M Radiometer for Measuring Particle Doses in Space and on Aircraft

E.G. Stassinopoulos, C.A. Stauffer, T.P. Dachev, G.J. Brucker, B.T. Tomov, and P.G. Dimitrov

This paper describes work performed and preliminary measurements taken in establishing proof-of-concept and reliability of the LIULIN-3M instrument, in preparation of a research effort for an invited paper—MEASUREMENT OF RADIATION EXPOSURE ON COMMERCIAL AIRCRAFT WITH THE LIULIN-3M INSTRUMENT—given at the Fifth European Conference on Radiation and Its Effects on Components and Systems.

Since its founding, NASA has been dedicated to the advancement of aeronautics and space science. The NASA Scientific and Technical Information (STI) Program Office plays a key part in helping NASA maintain this important role.

The NASA STI Program Office is operated by Langley Research Center, the lead center for NASA's scientific and technical information. The NASA STI Program Office provides access to the NASA STI Database, the largest collection of aeronautical and space science STI in the world. The Program Office is also NASA's institutional mechanism for disseminating the results of its research and development activities. These results are published by NASA in the NASA STI Report Series, which includes the following report types:

- **TECHNICAL PUBLICATION.** Reports of completed research or a major significant phase of research that present the results of NASA programs and include extensive data or theoretical analysis. Includes compilations of significant scientific and technical data and information deemed to be of continuing reference value. NASA's counterpart of peer-reviewed formal professional papers but has less stringent limitations on manuscript length and extent of graphic presentations.

- **TECHNICAL MEMORANDUM.** Scientific and technical findings that are preliminary or of specialized interest, e.g., quick release reports, working papers, and bibliographies that contain minimal annotation. Does not contain extensive analysis.

- **CONTRACTOR REPORT.** Scientific and technical findings by NASA-sponsored contractors and grantees.

- **CONFERECE PUBLICATION.** Collected papers from scientific and technical conferences, symposia, seminars, or other meetings sponsored or cosponsored by NASA.

- **SPECIAL PUBLICATION.** Scientific, technical, or historical information from NASA programs, projects, and mission, often concerned with subjects having substantial public interest.

- **TECHNICAL TRANSLATION.** English-language translations of foreign scientific and technical material pertinent to NASA's mission.

Specialized services that complement the STI Program Office's diverse offerings include creating custom thesauri, building customized databases, organizing and publishing research results... even providing videos.

For more information about the NASA STI Program Office, see the following:

I. INTRODUCTION

The LIULIN-3M is a "Low-LET Radiation Spectrometer" (LoLRS). It evolved from an international cooperative project by a group of Bulgarian, Russian, German, and American Scientists. The radiometer is a low-power, small size, lightweight, and low-cost instrument composed of a solid state detector (SSD) with supporting electronics that enable it to operate as a pulse height analyzer of energy deposited in the detector, and to obtain from these measurements the total dose or the dose rate produced by charged particles. A flash memory allows self-storage of data during flights and post flight retrieval [1,2,3,4].

II. DESCRIPTION

The basic detector is a Silicon-Lithium Drifted diode, 1 mm thick, with a sensitive area of 1 cm², and a weight of 0.232 g. Figure 1 contains a block diagram that shows the supporting electronics. Charge pulses generated from the energy deposited by incident particles are passed to the charge-sensitive amplifier, then to the discriminator and peak hold detector, and finally, they are converted from analog to digital signals by the 8-bit ADC (Analog-to-Digital Converter) and sorted into 256 channels, according to their voltage amplitudes. Two microprocessor units manage the data flow to and out of the memory devices.

The specifications and dynamic ranges of the instrument are listed in Table 1. The energy deposited or loss in silicon by the incident particles ranges from 0.16 to 13.8 MeV. The measurement time per spectrum of the instrument can be varied from 30 s to 30 min. The LIULIN-3M operates in two modes, namely, "Working Mode" and "Data Transfer Mode." In the Working Mode, the switch "ON" button connects the instrument via a jack to a polarized relay. In this mode the device is operating under the control of the program in the microprocessors to collect dose, flux, and spectra until the memory is filled. At that time, the instrument is automatically turned "OFF" through the relay. The total time spent in the Working Mode is 480 hours. The expected lifetime of the lithium batteries is about 1000 hours.

In the Transfer Mode the device is switched "ON" after it is delivered to the principal investigator. This mode allows the transfer of the accumulated data in the flash memory to a personal computer (PC) under a parallel port communication link. During this mode the data are correlated to the real time of the flight.

The major parameter of the instrument is the amplitude of the charge pulses generated in the solid-state detector by the incident particles.

Figure 1. LIULIN Block Diagram
They are then passed to the charge-sensitive amplifier that converts them to corresponding voltage pulses. The sensitivity or conversion factor of this amplifier is 240 mV/MeV. The threshold setting of the discriminator is 38.7 mV which establishes the lower data limit and consequently, the number of channels assigned to noise signals. Since there are 256 channels in the Analog-to-Digital converter and the upper voltage limit is 3.3 V, the sensitivity per channel is 3.3/256 = 12.89 mV/Ch and thus the first three channels are assigned to storing noise pulses. The deposited energy (Dep E) is given by equation

\[
\text{Dep E(MeV)} = \sum_{i=4}^{256} (\text{counts}_i \times \text{channel}) \times M
\]  

where the conversion factor \( M \) is given by:

\[
M = \left( \frac{12.89 \text{ mV}}{\text{Ch}} \right) \left( \frac{240 \text{ mV}}{\text{MeV}} \right) = 0.05371 \frac{\text{MeV}}{\text{Ch}}
\]  

and the corresponding dose rate per hour by:

\[
\text{Dose Rate} = K \times \text{Dep E (MeV)/}t_c
\]

where \( t_c \) is the collection time (in seconds) and the conversion factor \( K \) is:

\[
K = 2.486 \text{ in units of } \mu\text{Gy/}h \text{ / MeV}
\]

III. RESULTS

All data presented herein were collected on commercial flights every five minutes but the conditions of the measurements were not systematically controlled, particularly in terms of location and altitude. Figure 2 is a plot of dose rate versus minutes after the instrument was turned on for a flight from Washington, D.C., to Los Angeles, Calif. Figure 3 covers the trip from Los Angeles to Auckland, New Zealand, and Figure 4 shows the last leg of the flight from Auckland to Christchurch, New Zealand.

Figures 5, 6, and 7 represent plots of measurements for flights from Washington, D.C., to Denver, Colo., Denver to Houston, Texas, and finally, Houston to Denver, then back to Washington the same day, respectively. Figure 8 is a summary plot of these four flights. Figures 9 and 10 show data taken on flights from Washington, D.C., to Paris, France, and also on the return flight.

Figure 11 contains a plot of the instrument's measurements of dose rate versus time after turn-on for the Sofia-New York flight, indicating the background at the airport and the three data points for which the altitude levels are given. Figure 12 contains a plot of the data showing a curve fit to the four available data points versus altitude. Figure 13 depicts the data for the flights from Washington to Budapest. The measurements obtained on the return flight segments are plotted in Figure 14.

In most of the commercial flights, altitude information was made available by the airlines after the flights; however, for the trip from Sofia, Bulgaria, to New York, New York, altitude data were provided to members of the LIULIN team on board the plane by the pilot on three occasions, while on a recent flight from Washington, D.C., to Frankfurt, Germany, to Budapest, Hungary, flight information (latitude, longitude, altitude, speed, temperature) was continuously presented on TV monitors in the cabin. It should be noted, however, that for some flights altitude data could not be obtained.

Table 2 presents the total doses measured for travel between the indicated cities.

IV. DISCUSSION

For all flights reported in Figures 2 to 14, the peak dose rates are a function of two variables: altitude and magnetic latitude. Thus, in Figure 2 for the trip from Washington to Los Angeles the peak rate reached almost 0.2 \( \mu\text{Gy/}5\text{-min} \).
whereas in Figure 3 for the trip from Los Angeles to Auckland, the dose rate remained around 0.07 μGy/5-min for the major part of the flight over the Pacific Ocean, and only climbed to a peak of about 0.12 μGy/5-min near the end of the trip (last 2.5 hours). The dose rate for the short flight from Auckland to Christchurch, Figure 4, peaked at about 0.09 μGy/5-min.

In this context, particularly interesting are the measurements from the Los Angeles to Auckland flight, shown in Figure 3. The low dose rates would imply a correspondingly low altitude, perhaps 30000 ft, but the airline confirmed that this specific flight took place at an altitude of 39000 ft.

These measurements confirm that, as expected, flights toward lower magnetic latitudes, that is toward the magnetic equator, will experience smaller doses. The reason is that only a few very high energy galactic cosmic rays (several GeV/nucleon) can penetrate to those regions of the globe on account of the Earth’s magnetic field which deflects most arriving particles with lower energies (rigidity concept). The low dose rates shown in Figure 3 are probably due to the shielding effects of the Earth’s magnetic field which compensated for the normally higher cosmic ray progeny distribution at the elevated altitude of this flight.

The peak rates during the two flights covered in Figures 5 and 6, Washington-Denver-Houston, were about 0.15 and 0.13 μGy/5-min respectively. During the return trip, however, the peak rates achieved a surprisingly high level of 0.19 μGy/5-min for the Houston-Denver segment and 0.28 μGy/5-min for the Denver-Washington segment, as shown in Figure 7. The summary of
these four flights is shown in Figure 8. The altitude of the aircraft, as given to us at a later
date by the airline, was highest on the Houston–Denver (35000 ft) and Denver–Washington
flights (37000) compared to the Washington–Denver (35000 ft) and Denver–Houston (33000
ft) flight. It remains to be determined why the short duration Houston–Denver flight at 35000 ft
experienced a higher dose rate (by ∼ 20%) than the Washington–Denver flight at the same alti-
tude but of much longer duration.

Figures 9 and 10 show data for a trip to Paris,
France, and return to Washington, D.C., respec-
tively. The longer flight time of about 6 hours
shows that the rate was about constant for the
flight to Paris, approximately 0.18 μGy/5-min,
but on the return to Washington a constant rise in
rate is observed, with a peak of about 0.23 μGy/
5-min at the end of the trip as shown in Figure
10. Since we have no reliable altitude informa-
tion for these flights, it is difficult to interpret the
data correctly.
The flight from Sofia to New York provided for the first time an opportunity to measure the variation of the instrument’s response in real-time as a function of altitude through the cooperation of the pilot. Figure 11 shows a plot of dose rate versus time after turn-on. During the trip to New York the plane flew at three different altitudes of 31000, 35000, and 37000 ft. It can be seen that the detector measured three distinct dose rates. These three rates are plotted in Figure 12 versus altitudes, including the background rate on the ground. A curve fit was made to the four data points and extrapolated to 40000 ft where the dose rate approaches 0.5 μGy/5-min.

In Figures 13 and 14 for the trip to Frankfurt-Budapest and return, again a similar pattern was observed as that seen in Figures 9 and 10 for the Washington-Paris and Paris-Washington flights, namely the trips east to Paris (Fig. 9) and to Frankfurt (Fig. 13) indicate a relatively constant level of exposure rate during the transatlantic voyage, whereas both return trips west show a gradual increase in the dose rate as the flights progress. Assuming that the flight corridor is the same for both directions, it is conjectured that the variation is altitude dependent, that is, lower altitudes going east and gradually higher altitudes going west, maybe in consideration of the jet stream (?). This will be investigated and resolved in a follow-on paper.
All figures show low "background" measurements on the ground before take-off and after landing, ranging from 0.017 to 0.033 μGy/5-min. Upon close examination it is apparent that the data from low-altitude locations like Washington, Houston, and Los Angeles, with elevations less than 100 ft, have almost the same values as data from elevated locations as, for example, Snowmass, Colo., at over 9000 ft altitude (see Fig. 8), that is, average of about 0.0208 μGy/5-min and 0.0225 μGy/5-min, respectively. We had expected to observe a larger difference at these two altitudes. The normal global average rate of radiation background levels, excluding high concentrations of naturally occurring radionuclides such as radium, thorium, uranium, etc., has been reported to be about 0.008 to 0.017 μGy/5-min at about 1 meter above ground and including cosmic ray contributions coming from above [5]. It has been established that the detector orientation has no discernible impact on the measurements, in flight or on the ground.

The total dose accumulation for each traveled flight segment has been calculated and is presented in Table 2. While scheduled airlines are supposed to follow established flight corridors and altitudes, many times changes are made along the way because of safety, traffic, or weather conditions. Therefore, nominal flight plans, issued before the actual departure, which often may be delayed, are of no help in correctly analyzing and interpreting the measurements in terms of magnetic rigidity (cutoff latitude) and altitude. For this purpose, a “corrected” flight plan is required which indicates for every course change the exact location (geographic coordinates), altitude, zulu time, with several additional interim positional “fixes." This type of data was not available for the initial flights discussed in the present paper but is now systematically being obtained for long-range global mapping purposes.

As additional data are being accumulated over global distances with large longitudinal and latitudinal variations, a comparison to some predictions of cosmic ray intensities and their progeny may be possible, not only in terms of altitude but also as a function of rigidity and geomagnetic shielding affects.

Therefore, in Table 2 we present only the total accumulated dose for each flight, the flight duration in minutes, and the average dose per minute. The highest exposure occurred on the Denver, Colo., to Washington, D.C., trip (3.84 x 10^2 μGy/m) and the lowest on the Auckland, New Zealand, to Christchurch, New Zealand, segment (1.10x10^2 μGy/m), a factor of about 3.5 different. Other high doses were experienced on the Washington–Paris/Paris–Washington and the Washington–Frankfurt/Frankfurt–Washington flights. This is probably due to the fact that all of these flights traveled some of their time at high magnetic latitudes.

V. CONCLUSIONS

The LIULIN-3M instrument is an effective radiation monitor for aviation or space application. It is characterized by small size, low power, light weight, and low cost. The instrument is currently being used to perform global surveys of radiation environment levels within aircraft and on high-altitude balloon missions over the South Pole (U.S. Antarctic Program). Measurements from a multitude of commercial airline flights conducted so far indicate a strong altitude and magnetic latitude dependence, as predicted by theory. The maximum dose rate encountered until now is about 0.3 µGy per 5-minute interval.

VI. REFERENCES

This paper reports on the development of a compact radiation monitor/dosimeter, the LIULIN-3M, and on extended measurements conducted on the ground and on commercial aircraft on domestic and international flights.
