Abstract

In this paper, we present a new approach to constructing a “self-avoiding” walk through a triangular mesh. Unlike the popular approach of visiting mesh elements using space-filling curves which is based on a geometric embedding, our approach is combinatorial in the sense that it uses the mesh connectivity only. We present an algorithm for constructing a self-avoiding walk which can be applied to any unstructured triangular mesh. The complexity of the algorithm is \( O(n \cdot \log(n)) \), where \( n \) is the number of triangles in the mesh. We show that for hierarchical adaptive meshes, the algorithm can be easily parallelized by taking advantage of the regularity of the refinement rules. The proposed approach should be very useful in the runtime partitioning and load balancing of adaptive unstructured grids.

1 Introduction

Advances in adaptive software and methodology notwithstanding, parallel computational strategies will be an essential ingredient in solving complex, real-life problems. However, parallel computers are easily programmed with regular data structures; so the development of efficient parallel adaptive algorithms for unstructured grids poses a serious challenge. An efficient parallelization of these unstructured adaptive methods is rather difficult, primarily due to the load imbalance created by the dynamically-changing nonuniform and irregular grid. Nonetheless, it is generally believed that unstructured adaptive-grid techniques will constitute a significant fraction of future high-performance supercomputing. Mesh adaption and dynamic load balancing must be accomplished rapidly and efficiently, so as not to cause a significant overhead to the numerical simulation.

Serialization techniques play an important role in all parts of a Finite Element Method (FEM) over adaptive unstructured grids. A numbering of the unknowns allows for a matrix-vector notation of the underlying algebraic equations. Special numbering techniques (Cuthill-McKee, frontal methods) have been developed to optimize memory usage and locality of the algorithms. On the other hand, in many cases, runtime support for decomposing dynamic adaptive grid hierarchies is based on a linear representation of the grid hierarchy [8] in the form of a space-filling curve. Salmon et al. [10, 11] have demonstrated the successful application of techniques based on space-filling curves to N-body simulations. Other researchers [4, 6, 7, 8, 9] have also shown how space-filling curves can be used for graph partitioning and similar graph-related problems.

The general idea of a space-filling curve is a sort of a serialization (or linearization) of visiting points in a higher-dimensional space. A standard method for the construction is to embed the object of study into a regular environment (where the standard space-filling curves live). This approach introduces a kind of an “artificial” structure in the sense that the entire construction
depends on the embedding.\footnote{It is similar to describing metric properties of a curved surface in terms of a parametrization in the enveloping (uncurved) three space instead of doing inner geometry, i.e., geometry based only on measurements on the surface itself. The only inner properties of a mesh are its decomposition into cells of different dimensions and a face relation describing how the cells are glued together.} Furthermore, this type of a linear representation forgets about the combinatorial structure of the mesh which drives the formulation of operators between the finite element spaces. The questions arises whether one could reduce the different requirements for a serialization in an adaptive FEM over unstructured grids to a common denominator.

In this paper, we present a new approach to constructing a “self-avoiding” walk\footnote{This term should be familiar to people working in Monte Carlo methods; however, it is beyond the scope of this paper to address the similarities and differences in detail.} through a triangular mesh. Unlike the popular approach of visiting mesh elements using space-filling curves which is based on a geometric embedding, our approach is combinatorial in the sense that it uses the mesh connectivity only. We present an algorithm for constructing a self-avoiding walk which can be applied to any unstructured triangular mesh. The term unstructured refers to information that can hardly be compressed, and which does not contain any symmetry or redundancy. At this level, any labeling or numbering of the mesh components is as good (or as bad!) as any other scheme. However, the situation changes if the mesh adaption is done in a hierarchical manner where we, based on a set of simple rules for coarsening and refinement, pay particular attention to the triangulation of the initial mesh. In contrast with a general adaption scheme that produces just another unstructured mesh, this strategy exploits the structure of the adaption hierarchy to simplify the labeling process. We would like to modify (or adapt) the labeling only in regions where the mesh has been altered but not rebuild the entire indexing. This idea has been extensively developed in [3].

Self-avoiding walks can be used to improve the efficiency of the respective algorithms, in particular locality and load balancing. However, we need to search for some special classes of self-avoiding walks that will facilitate runtime load balancing with good locality in terms of memory access or communication. Since we are not interested in just any kind of walks, we have to first tackle the question of the existence of walks with the desired properties. In this paper, we give an existence proof which is constructive in nature so that it also provides an algorithm for generating such walks. For the case of hierarchical adaptive refinement, the proposed algorithm is easily amenable to parallelization. In the process of deriving the existence of a particular class of walks, a natural mathematical framework emerges which, we believe, can be easily adapted for other special classes of walks.

In Section 2, we define a certain class of walks whose existence for arbitrary unstructured meshes we can prove (see Appendix A). In Section 3, we present an algorithm based on the existence proof and show some sample results. The algorithm works for arbitrary unstructured meshes; however, a parallelization is non-trivial and the walk has to be completely rebuilt after mesh adaption. Furthermore, since we cannot make any regularity assumptions, the chances are quite low that we could prove the existence of constrained (in the sense of boundary conditions) walks. In Section 4, we briefly review hierarchical mesh adaption and a suitable indexing scheme. We find the missing regularity that enables us to prove the existence of constrained walks (see Appendix B) and to formulate a truly parallel algorithm for the construction of walks which is well-behaved with respect to mesh adaption. Section 5 concludes the paper with some perspectives.
2 Definitions

Consider an arbitrary two-dimensional triangular mesh $\mathcal{M}$ and denote the underlying set of triangles by $H$. Let $\#H$ denote the cardinality of $H$.

**Definition 2.1.** A mapping
\[
\omega : \{1, \ldots, \#H\} \rightarrow H
\]
is called a *self-avoiding walk* $\iff \omega$ is a bijection and
\[
\forall i \in \{1, \ldots, \#H - 1\} \quad \omega(i) \text{ and } \omega(i + 1) \text{ share an edge or a vertex.}
\]

**Remark.** The previous definition states that a walk visits each triangle exactly once and that *jumps* (i.e., two consecutive triangles in the walk that have an empty intersection) are forbidden. The reader may wonder why our requirements for a walk (cf. Eq. (2)) are rather weak. As simple examples show, the condition that triangles following one another must share an edge, is too strong. Generally, self-avoiding walks do not exist under this assumption (cf. Fig. 1 for a trivial example).

![Figure 1: A simple counterexample (look at the dual graph!)](image)

In the following, we consider a special class of self-avoiding walks.

**Definition 2.2.** A self-avoiding walk is called *proper* $\iff$
\[
\forall i \in \{2, \ldots, \#H - 1\} \quad \omega(i - 1) \cap \omega(i) \neq \omega(i) \cap \omega(i + 1).
\]

**Remark.** The previous definition states that for three triangles following one another in a proper self-avoiding walk, "jumping" twice over the same vertex is forbidden (cf. Fig. 2).

![Figure 2: A forbidden jump.](image)

*By a mesh we understand a simplicial complex coming from the simplicial decomposition of a connected 2D manifold (with or without a boundary).*
3 Existence

Proposition 3.1. There exists a proper self-avoiding walk for an arbitrary triangular mesh \( \mathcal{M} \).

For a proof of Proposition 3.1, we refer the reader to Appendix A. The proof is inductive over the number of triangles in the mesh and extends an existing proper self-avoiding walk over to a larger mesh. The proof provides a set of elementary rules which can be used to formulate an algorithm for constructing proper self-avoiding walks over arbitrary unstructured meshes. The value of such rules becomes apparent if practical questions such as the proper extension of existing “incomplete” walks are addressed (and the difficulty of the proof is in this part).

3.1 The Basic Algorithm

The proof of Proposition 3.1 provides an algorithm for the construction of proper self-avoiding walks: starting from an arbitrary triangle of \( \mathcal{M} \), choose new triangles sharing an edge with the current “subcomplex” and extend the existing proper self-avoiding walk over the new triangle. This algorithm can be represented recursively. Figure 3 shows the pseudo-code for the basic function, called EXTEND\_WALK. The algorithm begins with the selection of an arbitrary triangle from the mesh. After removing this triangle from the mesh and inserting it (as the first triangle) into the walk, the function EXTEND\_WALK is called with \( P \) being the position of the first triangle in the walk.4

![Figure 3: The basic function.](image)

The complexity of this algorithm is \( O(n \cdot \log(n)) \), where \( n \) is the number of triangles in the mesh. This complexity is obtained as follows. Since we organize our triangles in a red-black tree, a search in this structure is of complexity \( O(\log(n)) \). The edge-triangle incidence relation can also be organized in a red-black tree. Since we have to perform this search for each triangle in our mesh, the overall complexity of our algorithm is \( O(n \cdot \log(n)) \).

Given the existence of proper self-avoiding walks, other approaches might be favorable. For example, self-avoiding walks have a long tradition in the application of Monte Carlo methods to study long-chain polymer molecules. However, this is not the focus of this paper.

---

4By a position in a walk, we mean a reference to a triangle in the walk rather than an index. We need a data structure with fast insertion; therefore, an array is not appropriate. In our C++ implementation, a position is given by list\langle Triangle\rangle::iterator.
3.2 Results

We implemented a sequential algorithm for the generation of a proper self-avoiding walk using the set and map containers from the C++ Standard Template Library which is part of the ANSI-C++ standard. Both containers are implemented with red-black trees. The results presented in Tables 1 and 2 were obtained for some sample meshes on a 110 MHz microSPARC II using GNU’s g++ compiler (version 2.7.2.3) with the -0 flag. Note that the times in the tables below include the setup time for the mesh and the edge-triangle incidence structure.

Table 1: Runtimes for various mesh sizes. Table 2: Runtimes for various triangle/edge ratios.

The results in Table 1 indicate the dependence of the runtime on the number of triangles (or edges). According to our description of the algorithm, the runtime may also depend on the triangle/edge ratio. The results in Table 2 explore this possibility; however, the numbers clearly show that the dependence of the execution time on the triangle/edge ratio is negligible and confirm our complexity estimate for the whole algorithm.

4 Optimization and Parallelization

A standard parallelization of the deterministic algorithm would be based on the observation that if the proper extensions of a self-avoiding walk for two triangles do not interfere with each other, then they can be done in parallel. Such an approach is feasible in dealing with single meshes, when no additional structural information is available, or with families of meshes without any hierarchical structure, although this procedure might be computationally expensive in connection with adaption.

For a extended discussion of unstructured mesh adaption, we refer the reader to [1, 5]. In the following, we restrict ourselves to the case of hierarchical refinement and apply the standard 1:4 (red) and 1:2 (green) subdivision rules for triangles (cf. Fig. 4).

A couple of additional rules are then applied, primarily to assure that the quality of the adapted mesh does not deteriorate drastically with repeated refinement:

1. All triangles with exactly two bisected edges have their third edge also bisected. Thus, such triangles are isotropically refined.
2. A green triangle cannot be further subdivided. Instead, the previous subdivision is discarded and isotropic subdivision is applied to the (red) ancestor triangle.

One might also think about an implementation using hash tables.

---

5One might also think about an implementation using hash tables.
Figure 4: The left picture shows the isotropic subdivision of a triangle. The right one gives an example of anisotropic subdivision.

For hierarchical meshes a completely different approach to constructing proper self-avoiding walks is possible: the general algorithm has to be applied only once to the initial mesh and this "coarse" self-avoiding walk can be reused after adaption. On the local level, we are going to exploit the regularity of the refinement rules. This leads us to the consideration of constrained self-avoiding walks. Local regularity allows us to prove the existence of solutions for the underlying "boundary value problems". (In that sense, the algorithm derived from the proof of Proposition 3.1 guarantees the solvability of "initial value problems" only.) In the next section, we sketch a technique which allows the efficient handling of constraints.

4.1 An Indexing Technique for Hierarchical Meshes

It is the task of an index scheme to properly name or label the various objects (vertices, edges, triangles) of a mesh. We prefer the term index scheme instead of numbering to stress that the use of natural numbers as indices is not sufficient to meet the naming requirements of the FE objects on parallel architectures. For a detailed discussion, refer to [2, 3].

Our index scheme is a combination of coarse and local schemes. The coarse scheme labels the objects of the coarse mesh in such a way that the incidence relations can be easily derived from the labels. The vertices are enumerated starting from 1. For the example in Fig. 5, the set of vertices for the coarse triangulation consists of the following numbers:

\[\text{vertices} = \{1, 2, 3, 4, 5, 6, 7, 8\}\]

Figure 5: An L-shaped domain and its coarse triangulation.

The edges of the coarse triangulation are indexed by ordered pairs of integers that correspond to the endpoints of the edges. The ordering is chosen so that the first index is less than the
second one. For the example in Fig. 5, the set of coarse edges consists of the following pairs:

\[ \text{edges} = \{(1,2), (1,3), (1,5), (2,5), (3,4), (3,5), (3,6), (4,6), (5,6), (5,7), (5,8), (6,7), (7,8)\}. \]

The same principles are applied to index the coarse triangles. They are denoted by the triple consisting of their vertex numbers in ascending order. Thus, the set of coarse triangles reads:

\[ \text{triangles} = \{(1,2,5), (1,3,5), (3,4,6), (3,5,6), (5,6,7), (5,7,8)\}. \]

Note that this index scheme can be applied to elements with curved boundaries as well.

The ideal model for local considerations is given by the two-dimensional standard simplex \( \sigma^2 \) (cf. Fig. 6):

\[
\sigma^2 := \{(x_1, x_2, x_3) \in \mathbb{R}^3 \mid x_1 + x_2 + x_3 = 1\}. \tag{4}
\]

![Figure 6: The two-dimensional standard simplex and some points on it.](image)

The local scheme exploits the regularity (and the finiteness) of the refinement rules to produce names for the objects at subsequent refinement levels \([3]\). We use (scaled) natural coordinates as indices in the local scheme. Again, this is done in a way such that incidence relations and the refinement level are encoded in the indices of the objects (cf. Fig. 7). For example, the set of vertices at level \(k\) in the local model is given by:

\[
V_k(\sigma^2) := \{(a,b,c) \in \mathbb{N}^3 \mid a + b + c = 2^k\}. \tag{5}
\]

Obviously, there holds \(v \in V_k(\sigma^2) \iff 2v \in V_{k+1}(\sigma^2)\) and therefore we have the following embedding \(V_k(\sigma^2) \subset V_{k+1}(\sigma^2)\). This shows that we can easily move between refinement levels by rescaling.

Denote by \(E_k(\sigma^2)\) the set of edges at level \(k\). We choose the integer triple corresponding to the midpoint of an edge as its index. Hence \(E_k(\sigma^2) \simeq V_{k+1}(\sigma^2) - V_k(\sigma^2)\) and

\[
E^{(k)} = E^{(k)}(\sigma^2) := \bigcup_{i=0}^{k} E_i(\sigma^2) \implies E^{(k)} \simeq V_{k+1}(\sigma^2) - V_0(\sigma^2). \tag{6}
\]
Denote by $T_k(\sigma^2)$ the set of triangles on level $k$ (red and green) and let

$$T^{(k)} = T^{(k)}(\sigma^2) := \bigcup_{i=0}^{k} T_i(\sigma^2).$$

(7)

We choose the integer triples corresponding to the barycenter of a triangle as its index.

The coarse and local schemes are combined by taking the union of the Cartesian products of the coarse mesh objects with their corresponding local schemes. Ambiguities are resolved by using a normal form of the index. The key features of such a scheme are:

- Each object is assigned a global name that is independent of any architectural considerations or implementation choices.
- Combinatorial information is translated into simple arithmetic.
- It is well-behaved under (adaptive) refinement. No artificial synchronization/serialization is introduced.
- It can be extended (with appropriate modifications) to three dimensions [3].

4.2 Constrained Self-Avoiding Walks

We call a subset $T \subset T^{(k)}(\sigma^2)$ a local refinement of $\sigma^2$ if it can be obtained by applying the refinement rules described in section 4.6. The refinement level of a coarse triangle is defined to be zero. For an arbitrary triangle, the refinement level is defined as the successor of the refinement level of the parent triangle (the triangle it was created from by subdivision). The refinement level of a triangulation is defined to be maximum of the refinement levels of its triangles [3]. We denote the level of a triangulation $T$ by $l(T)$.

The scheme developed in the previous section allows us, for the case of hierarchical refinement, to decompose our considerations into global and local cases. Here “global” means “related to the initial (coarse) mesh”, while “local” means “restricted to a triangle of the coarse mesh”. Given a walk over and a local refinement of the coarse mesh one might ask whether it is possible to extend the walk over the triangles of the local refinement. In addition, we would like to decouple the considerations for different coarse triangles. This leads naturally to what we call constrained self-avoiding walks: a walk over the initial mesh leaves a trace or footprint on

---

\(6\)Since we allow coarsening, the term “local refinement” is somewhat misleading. However, any local refinement obtained by a combination of coarsening and refinement can be obtained by refinement only, discarding the history of the adaption. This assumes that coarsening did not occur beyond the initial mesh.
each coarse triangle which is then translated into a "boundary value problem" for the extension of the self-avoiding walk. The regularity of the local picture allows us to prove the existence of constrained proper self-avoiding walks.

**Definition 4.1.** A pair \((\alpha, \beta) \in V_1(\sigma^2) \times V_1(\sigma^2)\) is called constraint on \(\sigma^2 \iff \alpha \neq \beta\).

**Remark:** The previous definition states that we forbid constraints requiring that a walk enters and leaves a triangle through the same edge or the same vertex. (The latter would imply a forbidden jump in the "coarse" walk.) In the definition, we implicitly used the embedding \(V_0(\sigma^2) \subset V_1(\sigma^2)\) and the isomorphism \(E_{0}(\sigma^2) \simeq V_1(\sigma^2) - V_0(\sigma^2)\). Figure 8 shows a few examples of constraints. The entry constraints are denoted with bullets and the exit constraints with filled triangles.

**Definition 4.2.** Let \(c = (\alpha, \beta)\) be a constraint on \(\sigma^2\) and \(T \subset T^{(k)}(\sigma^2)\) a local refinement of \(\sigma^2\). A proper self-avoiding walk \(\omega : \{1, \ldots, \#T\} \to T\) is called compatible with \(c \iff \alpha \subset \omega(1)\) and \(\beta \subset \omega(\#T)\).

**Lemma 4.1.** Let \(c = (\alpha, \beta)\) be an arbitrary constraint on \(\sigma^2\). Let \(R, G \in T_1(\sigma^2)\) be a red and green triangle, respectively. There exist proper self-avoiding walks on \(R\) and \(G\) which are compatible with \(c\).

**Remark:** Lemma 4.1 can be easily proved and is valid not only for constraints on \(\sigma^2\) and \(R, G \in T_1(\sigma^2)\), but also for constraints on red and green triangles at any level, since the proof of Lemma 4.1 depends only on the fact whether a triangle is red or green.

Obviously, the formulation of constraints is not restricted to coarse triangles, i.e., triangles at level zero. A slightly more general definition than definition 4.1 goes as follows:

**Definition 4.3.** Let \(k \in \mathbb{N}, k > 0\). A pair \((\alpha, \beta) \in V_k(\sigma^2) \times V_k(\sigma^2)\) is called constraint on \(t \in T_{k-1}(\sigma^2) \iff \alpha \neq \beta\).

**Proposition 4.1.** Let \(c = (\alpha, \beta)\) be an arbitrary constraint on \(\sigma^2\) and \(T \subset T^{(k)}(\sigma^2)\) be a local refinement of \(\sigma^2\). There exists a proper self-avoiding walk \(\omega_{T,c}\) on \(T\) which is compatible with \(c\).

Given a constraint on \(\sigma^2\) and a local refinement \(T \subset T^{(k)}(\sigma^2)\), Proposition 4.1 guarantees the existence of a compatible proper self-avoiding walk. The proof in Appendix B also provides an algorithm for constructing the solution of this "boundary value problem". The synthesis of Propositions 3.1 and 4.1 provides a simple parallel algorithm which requires changing an existing proper self-avoiding walk only where the mesh has been adapted (coarsened/refined). If the mesh adaption affected only levels higher than \(k\), the walk has to be modified only over triangles whose level is greater than \(k\). Note that the local adaption of the walk are decoupled from one another and can be done independently; thus, this is a truly parallel algorithm.
5 Conclusions and Perspectives

In this paper, we have developed a theoretical basis for the study of self-avoiding walks over two-dimensional adaptive unstructured grids. We described an $O(n \cdot \log(n))$ algorithm for the construction of proper self-avoiding walks over arbitrary unstructured meshes and reported results of a sequential implementation. We discussed parallelization issues and suggested a significant improvement for hierarchical adaptive unstructured grids. For this situation, we have also proved the existence of constrained proper self-avoiding walks.

The algorithms presented allow a straightforward generalization to tetrahedral meshes; however, there is some flexibility because of additional freedom in three-space. The application to load balancing is likewise rather straightforward. However, modifications to improve locality in the sense of a generalized frontal method requires a more detailed study of the relationships between (more specialized) constraints on walks and cache memory behavior.

References

A Proof of Proposition 3.1

Before we start with the proof of Proposition 3.1, we remind the reader of two technical results. The respective proofs are not very difficult, but beyond the scope of this paper.

**Lemma A.1.** Let \( t, t_1, t_2, t_3 \) be triangles in a mesh \( \mathcal{M} \) and

\[
\forall i \in \{1, 2, 3\} \quad t_i \mid t. \tag{9}
\]

Then either

\[
t_1 \cap t_2 \cap t_3 = \emptyset \tag{10}
\]

or \( \mathcal{M} \) is tetrahedral (cf. Fig. 9). \( \square \)

(Note that if two triangles in a mesh share two vertices they must share the corresponding edge.)

Figure 9: A tetrahedral mesh.

**Lemma A.2.** Let \( \mathcal{M} \) be a mesh. There exists a triangle \( \tau \) in \( \mathcal{M} \) such that \( \mathcal{M} - \tau \), the complex obtained by removing \( \tau \) from \( \mathcal{M} \), is still a mesh. \( \square \)

We use the following notation. If two triangles \( t_1, t_2 \) share an edge, we write \( t_1 \mid t_2 \). Let \( \omega \) be a self-avoiding walk. If \( \omega(i) \mid \omega(i + 1) \), we will write \( \omega(i) \leftarrow \omega(i + 1) \) indicating that \( \omega \) enters \( \omega(i + 1) \) from \( \omega(i) \) over an edge. If \( \omega(i) \nmid \omega(i + 1) \), we write \( \omega(i) \swarrow \omega(i + 1) \) indicating that \( \omega \) jumps into \( \omega(i + 1) \) from \( \omega(i) \) over a vertex.

**Proof of Proposition 3.1:** We prove Proposition 3.1 by induction over the number of triangles.

Assume that there exist proper self-avoiding walks for meshes with \( n \) triangles. Let \( \mathcal{M} \) be a mesh with \( n + 1 \) triangles.

Let \( \tau \) be a triangle in \( \mathcal{M} \) such that \( \mathcal{M} - \tau \), the mesh consisting of all the triangles in \( \mathcal{M} \) except \( \tau \), is a mesh (see Lemma A.2). Mesh \( \mathcal{M} - \tau \) has \( n \) triangles and hence, by our induction assumption, there exists a proper self-avoiding walk \( \omega_{\mathcal{M} - \tau} \). We show that \( \omega_{\mathcal{M} - \tau} \) can be extended to a proper self-avoiding walk \( \omega_{\mathcal{M}} \) for \( \mathcal{M} \). We call this \( \omega_{\mathcal{M}} \) a proper extension of \( \omega_{\mathcal{M} - \tau} \).

Let \( t \) be an triangle of \( \mathcal{M} - \tau \) sharing an edge with \( \tau \) (i.e. \( t \mid \tau \) holds). For an appropriate \( i \in \{1, \ldots, n\} \), there holds

\[
t = \omega_{\mathcal{M}} \cdot \tau(i). \tag{11}
\]

The discussion naturally can be split up into four cases, depending on whether \( \omega_{\mathcal{M} - \tau} \) enters \( t \) through an edge or a vertex and leaves through an edge or a vertex, respectively.
We omit the subscript \( \mathcal{M} - \tau \) from \( \omega \) in the following for the sake of clarity. If we do not know whether the transition from \( \omega(i) \) to \( \omega(i + 1) \) goes over an edge or a vertex, we write \( \omega(i) \rightarrow \omega(i + 1) \).

In the figures below, parts of \( \omega_{\mathcal{M} - \tau} \) are drawn as solid lines whereas the modifications leading to \( \omega_{\mathcal{M}} \) are drawn as dashed lines. Triangles are indexed by their position in the walk (e.g. \( \omega(i) \) is denoted by \( i \)).

**Case I: \( \omega(i - 1) \rightarrow \omega(i) \rightarrow \omega(i + 1) \)**

Figure 10 illustrates the modifications necessary if \( \omega_{\mathcal{M} - \tau} \) enters and leaves \( t \) through an edge.

![Figure 10](image)

**Figure 10:** Existing walk enters the triangle adjacent to \( \tau \) through an edge and leaves it through another edge.

- If \( \omega(i - 1) \cap \tau \neq \omega(i - 2) \cap \omega(i - 1) \), then \( \omega(i - 1) \rightarrow \tau \rightarrow \omega(i) \) is a proper extension of \( \omega \) (cf. Fig. 10(a)).

- If \( \omega(i - 1) \cap \tau = \omega(i - 2) \cap \omega(i - 1) \), then \( \omega(i - 2) \cap \tau = \omega(i - 1) \).
  - If \( \omega(i + 1) \cap \tau \neq \omega(i + 1) \cap \omega(i + 2) \), then \( \omega(i) \rightarrow \tau \rightarrow \omega(i + 1) \) is a proper extension of \( \omega \) (cf. Fig. 10(b)).
  - If \( \omega(i + 1) \cap \tau = \omega(i + 1) \cap \omega(i + 2) \), then \( \omega(i + 1) \cap \omega(i + 2) \).
    - If \( \omega(i - 1) \cap \tau \neq \omega(i + 1) \cap \omega(i + 2) \), then \( \omega(i - 2) \rightarrow \tau \rightarrow \omega(i) \rightarrow \omega(i + 1) \rightarrow \omega(i + 1) \) is a proper extension of \( \omega \) (cf. Fig. 10(c)).
    - Let \( \omega(i - 1) \cap \omega(i + 1) = \omega(i + 1) \cap \omega(i + 2) \). According to Lemma A.1, either \( \mathcal{M} \) is tetrahedral or \( \omega(i - 1) \cap \omega(i + 1) \cap \tau = \emptyset \). If \( \mathcal{M} \) is tetrahedral, there is nothing to prove. For the other case, we have \( \emptyset = \omega(i - 1) \cap \omega(i + 1) \cap \tau = \omega(i + 1) \cap \omega(i + 2) \cap \tau = \omega(i + 1) \cap \tau = \omega(i + 1) \cap \omega(i + 2) \). This is a contradiction with our assumption \( \omega(i + 1) \cap \tau \neq \omega(i + 2) \) which means \( \omega(i + 1) \cap \omega(i + 2) \neq \emptyset \). Therefore, if \( \mathcal{M} \) is not tetrahedral, the case \( \omega(i - 1) \cap \omega(i + 1) = \omega(i + 1) \cap \omega(i + 2) \) is not possible.\(^7\)

\(^7\) Obviously, there are proper self-avoiding walks for tetrahedral meshes. Note that a tetrahedral mesh cannot be a proper submesh of a larger 2D mesh which is a manifold as a topological space.
Case II: \( \omega(i-1) \vdash \omega(i) \cap \omega(i+1) \)

Figure 11 illustrates the modifications necessary if \( \omega_{\mathcal{M}} \tau \) enters \( t \) through an edge and leaves it through a vertex.

\[
\begin{align*}
&\text{(a)} \quad \text{(b)} \quad \text{(c)}
\end{align*}
\]

Figure 11: Existing walk enters the triangle adjacent to \( \tau \) through an edge and leaves it through a vertex.

- If \( \omega(i) \cap \omega(i+1) \subset \omega(i) \cap \tau \), then \( \omega(i) \vdash \tau \to \omega(i+1) \) is a proper extension of \( \omega \) (cf. Fig. 11(a)).

- Suppose \( \omega(i) \cap \omega(i+1) \notin \omega(i) \cap \tau \). (Note that \( \omega(i) \cap \omega(i+1) \) definitely consists of a single vertex!)
  - If \( \omega(i-1) \cap \tau \neq \omega(i-2) \cap \omega(i-1) \), then \( \omega(i-1) \vdash \tau \to \omega(i) \) is a proper extension of \( \omega \) (cf. Fig. 11(b)).
  - If \( \omega(i-1) \cap \tau = \omega(i-2) \cap \omega(i-1) \), then \( \omega(i-2) \cap \omega(i-1) \). In that case, \( \omega(i-2) \vdash \tau \vdash \omega(i) \vdash \omega(i+1) \) is a proper extension of \( \omega \) (cf. Fig. 11(c)).

Case III: \( \omega(i-1) \cap \omega(i) \vdash \omega(i+1) \)

Figure 12 illustrates the modifications necessary if \( \omega_{\mathcal{M}} \tau \) enters \( t \) through a vertex and leaves it through an edge.

\[
\begin{align*}
&\text{(a)} \quad \text{(b)} \quad \text{(c)}
\end{align*}
\]

Figure 12: Existing walk enters the triangle adjacent to \( \tau \) through a vertex and leaves it through an edge.
• If \( \omega(i - 1) \cap \omega(i) \subset \omega(i) \cap \tau \), then \( \omega(i - 1) \rightarrow \tau \vdash \omega(i) \) is a proper extension of \( \omega \) (cf. Fig. 12(a)).

• Suppose \( \omega(i - 1) \cap \omega(i) \notin \omega(i) \cap \tau \).
  - If \( \omega(i + 1) \cap \tau \neq \omega(i + 1) \cap \omega(i + 2) \), then \( \omega(i) \vdash \tau \rightarrow \omega(i + 1) \) is a proper extension of \( \omega \) (cf. Fig. 12(b)).
  - If \( \omega(i + 1) \cap \tau = \omega(i + 1) \cap \omega(i + 2) \), then \( \omega(i + 1) \vdash \omega(i + 2) \). In that case, \( \omega(i - 1) \rightarrow \omega(i + 1) \vdash \omega(i + 1) \vdash \omega(i + 2) \) is a proper extension of \( \omega \) (cf. Fig. 12(c)).

Case IV: \( \omega(i - 1) \cap \omega(i) \cap \omega(i + 1) \)

Figure 13 illustrates the modifications necessary if \( \omega_{\mathbb{R}-\tau} \) enters and leaves \( t \) through a vertex.

\begin{figure}[h]
\centering
\includegraphics[width=0.5\textwidth]{figure13}
\caption{Existing walk enters the triangle adjacent to \( \tau \) through a vertex and leaves it through another vertex.}
\end{figure}

• If \( \omega(i - 1) \cap \omega(i) \subset \omega(i) \cap \tau \), then \( \omega(i - 1) \rightarrow \tau \vdash \omega(i) \) is a proper extension of \( \omega \) (cf. Fig. 13(a)).

• If \( \omega(i - 1) \cap \omega(i) \notin \omega(i) \cap \tau \), then \( \omega(i) \vdash \tau \rightarrow \omega(i + 1) \) is a proper extension of \( \omega \) (cf. Fig. 13(b)).

Since we have been able to properly extend \( \omega_{\mathbb{R}-\tau} \) in all cases, our proposition is proved. \( \square \)

B Proof of Proposition 4.1

Proof: We prove Proposition 4.1 by induction over the level \( l(T) \) of \( T \). Lemma 4.1 is the starting point for our induction \( l(T) = 1 \).

Assume now that \( l(T) = n + 1 \). Let \( T' = T - (T \cap T_{n+1}(\sigma^2)) \). \( T' \) is a local refinement of \( \sigma^2 \) and \( l(T') = n \). This technique is known as hierarchical coarsening [2] (cf. Fig. 14).

By our induction assumption, there exists a proper self-avoiding walk \( \omega_{T',\sigma} \) which is compatible with \( \sigma \). We show that there is a proper extension \( \omega_{T',\sigma} \) of \( \omega_{T',\sigma} \).

\( T \) can be obtained from \( T' \) by local refinement. Let \( \tau \) be a triangle of \( T' \) which must be subdivided (red or green) in order to obtain \( T \). \( \omega_{T',\sigma} \) induces a constraint on the children of \( \tau \) or, in other words, the constraint on \( \tau \) is propagated to \( \tau \)’s children by \( \omega_{T',\sigma} \). This situation is illustrated in Fig. 15. Figure 15(a) shows a local refinement \( T \) and the given constraint \( (\alpha, \beta) \).
Figure 14: Four steps of hierarchical coarsening.

Figure 15(b) shows one step of hierarchical coarsening where we already have a proper self-avoiding walk $\omega_{T'}$. This self-avoiding walk induces constraints on the higher-level triangles as shown in Fig. 15(c)).

![Diagram showing constraints propagation](image)

Figure 15: Two steps of constraint propagation.

Since $\tau$ will be refined red or green, we can apply Lemma 4.1 (and the remark thereafter) to properly extend $\omega_{T'}$ over the children of $\tau$.

If we apply this procedure to all triangles $t \in T'$ which must be subdivided to get to $T$, we obtain $\omega_{T'}$.

This proves our proposition. □

Figure 16 shows an example for the correct extension of a proper self-avoiding walk to a higher level of refinement. Figure 16(a) shows the mechanical way dictated by the constraints. This walk can often be improved in the sense that certain jumps over vertices can be replaced by jumps over edges since the triangles under consideration share an edge (cf. Fig. 16(b)).
