ABSTRACT

A wide variety of solar system planetary bodies are now known to radiate in the soft x-ray energy (<5 keV) regime. These include planets (Earth, Jupiter, Venus, Saturn): bodies having thick atmosphere and with/without intrinsic magnetic field; planetary satellites (Moon, Io, Europa, Ganymede); bodies with no/thin atmosphere; and comets and Io plasma torus: bodies having extended tenuous atmosphere. Several different mechanisms have been proposed to explain the generation of soft x-rays from these objects, whereas in the hard x-ray energy range (>10 keV) x-rays mainly result from electron bremsstrahlung process. In this paper we present a brief review of the x-ray observations on each of the planetary bodies and discuss their characteristics and proposed source mechanisms.

1. INTRODUCTION

The energy range of x-ray photons typically spans 0.1-100 keV. Of this wide energy extent the soft x-ray energy band (<5 keV) is an important spectral regime for planetary remote sensing, as a large number of solar system objects are now known to shine at these wavelengths. These include Earth, Moon, Jupiter, Saturn, comets, Venus, Galilean satellites, Mars, Io plasma torus, and the Sun.

Since Earth's thick atmosphere efficiently absorbs x-ray radiation at lower altitudes (<30 km, even for hard x-rays), x-rays can only be observed from space by high-altitude balloons-, rockets-, and satellites-based instruments. But to observe most of the soft x-ray band one has to be above ~100 km from Earth's surface.

Terrestrial x-rays were discovered in the 1950s. The launch of first x-ray satellite Uhuru in 1970 marked the beginning of satellite-based x-ray astronomy. Subsequent launch of x-ray observatories - Einstein, and particularly Rontgensatellit (ROSAT'I'), made an important contribution to the planetary x-ray studies. With the advent of sophisticated x-ray observatories - Chandra and XMM-Newton, the field of planetary x-ray astronomy is advancing at a much faster pace.

Earth and Jupiter, as magnetic planets, are observed to emanate strong x-ray emissions from their auroral (polar) regions, thus providing vital information on the nature of precipitating particles and their energization processes in planetary magnetospheres [1,2,3]. X-rays from low latitudes have also been observed on these planets. Saturn should also produce x-rays in the same way as Jupiter, although the intensity is expected to be weaker. Lunar x-rays have been observed from the sunlit hemisphere; a small fraction of dayside x-rays are also seen from the Moon's nightside [4]. Cometary x-rays are now a well-established phenomena; more than a dozen comets have been observed at soft x-ray energies [5,6]. The Chandra X-ray Observatory (CXO) has recently captured soft x-rays from Venus [7,8]. Martian x-rays are expected to be similar to those on Venus. More recently, using CXO [9] have discovered soft x-rays from the inner moons of Jupiter - Io, Europa, and probably Ganymede. The Io Plasma Torus (IPT) is also discovered recently by CXO to be a source of soft x-rays [9]. High spatial resolution observations of Jovian x-rays by CXO/HRC-I
have recently revealed a mysterious pulsating (period ~45 minutes) x-ray hot spot in the northern polar regions of Jupiter that have called into question our understanding of Jovian auroral x-rays [10].

In this paper we will present an overview of the x-ray observations on planets, comets, and moons, and discuss the proposed emission production mechanisms.

2. EARTH

Auroral Emissions

Precipitating particles deposit their energy into the Earth's atmosphere by ionization, excitation, dissociation, and heating of the neutral gas. High-energy electrons or ions impacting the nucleus of atoms or molecules can lead to an emission of an x-ray photon by bremsstrahlung with an energy comparable to the energy of the incident particle. The x-ray bremsstrahlung production efficiency is proportional to $1/m^2$, where $m$ is the mass of the precipitating particle. This implies that electrons are $10^6$ times more efficient than protons to produce x-ray bremsstrahlung. The production efficiency is a non-linear function of energy, with increasing efficiency for increasing incident energies. For example, for a 200 keV electron the probability of producing an x-ray photon at any energy below 200 keV is 0.5%, while the probability for a 20 keV electron to produce an x-ray photon below 20 keV is only 0.0057% [11].

The main x-rays production mechanism in Earth's auroral zones is bremsstrahlung and therefore the x-ray spectrum of an aurora has been found to be very useful in studying the characteristics of energetic electron precipitation. [12,13,14]. Since the x-ray measurements are not contaminated by sunlight, the remote sensing of x-rays can be used to study energetic electron precipitation on the dayside as well as on the nightside of the Earth [15]. Characteristic line emissions for the main species of the Earth's atmosphere, Nitrogen ($K_a$ at 0.393 keV), Oxygen ($K_a$ at 0.524 keV) and Argon ($K_a$ at 2.958 keV, $K_b$ at 3.191 keV) will also be produced by both electrons and protons, but so far no x-ray observations have been made at energies where these lines are dominant compared to the x-ray bremsstrahlung.

X-ray photons from bremsstrahlung are emitted dominantly in the direction of the precipitating electron velocity. Consequently, the majority of the x-ray photons in Earth's aurora are directed towards the planet. These downward propagating x-rays, therefore, cause additional ionization and excitation in the atmosphere below the altitude where the precipitating particles have their peak energy deposition [e.g., 16,17]. A fraction of the x-ray emission that is moving away from the ground can be used to study the x-rays from satellite-based x-ray imagers, e.g., AXIS on UARS and PIXIE on POLAR.

Auroral x-ray bremsstrahlung has been observed from balloons and rockets since 1960s and from spacecraft since the 1970s [18,19,20,13]. Due to detector techniques that have been used, only x-rays above ~3 keV have been observed from the Earth's ionosphere. The PIXIE (Polar ionospheric X-Ray Imaging Experiment) aboard Polar is the first x-ray detector that provides true 2-d global x-ray image at energies >~3 keV [21]. Because of the high apogee of Polar satellite (~9 R_E), PIXIE is able to image the entire auroral oval with a spatial resolution of ~700 km for long duration when the satellite is around apogee. This has helped to study the morphology of x-ray aurora and its spatial and temporal variation, and consequently the evolution of energetic electron precipitation during magnetic storms (days) and substorms (1-2 hours). Based on data from the PIXIE camera, [22] showed that the x-ray substorm brightens up in the midnight sector and has a prolonged and delayed maximum in the morning sector due to the scattering of drifting electrons. Statistically the x-ray bremsstrahlung intensity peaks in the midnight substorm onset, is significant in the morning sector and has a void in the early dusk sector [23]. During the onset/expansion phase of a typical substorm the electron energy deposition rate is 60-90 GW, which produces 10-30 MW bremsstrahlung x-rays [24]. Combining the results of PIXIE with UV imager aboard Polar it is now possible to derive the energy distribution of precipitating electrons in the 0.1-100 keV range [14].

Fig.X1. X-ray image of Earth from the Polar PIXIE instrument for energy range 2.9-10.1 keV.

Non-Auroral

[Incomplete]

.....The non-auroral background x rays above 2 keV from the Earth is almost completely negligible except for brief periods during major solar flares [23]. During flares, solar x-rays light up the sunlit side of the Earth by Thomson
scattering, as well as by fluorescence of atmospheric argon to produce characteristic x-rays at 3 keV. The x-ray brightness can be comparable to that of a moderate aurora [23]. Although the fluxes were slightly larger than expected from NOAA GOES measurements they showed that the shape of the measured x-ray spectra was in fairly good agreement with modeled spectra of solar x-rays subject to Thomsen scattering in the Earth's atmosphere.

3. JUPITER

Auroral Emissions
The first detection of x-ray emissions from Jupiter was made by the satellite-based Einstein observatory in 1979 [25]. The emissions were detected in the 0.2-3.0 keV energy range from both poles of Jupiter. Analogous to the processes on Earth, it was expected that Jupiter's x-rays might originate as bremsstrahlung by precipitating electrons [26]. However, the power requirement for producing the observed emission with this mechanism \((10^{15}-10^{16} \text{ W})\) is more than two orders of magnitude larger than the input auroral power available as derived from Voyager and IUE observations of the ultraviolet aurora [cf.2]. Ref. [25] suggested a mechanism implying K-shell line emissions from precipitating energetic sulfur and oxygen ions from the inner magnetosphere, with energies in the 0.3-4.0 MeV/nucleon range. The heavy ions are thought to emit x-rays by first charge stripping to a highly ionized state, followed by charge exchange and excitation through collisions with \(\text{H}_2\). The bremsstrahlung process was further ruled out by theoretical models [27,28] showing that primary and secondary precipitating electrons in the 10-100 keV energy range are inefficient at producing the observed x-ray emissions.

Furthermore, during its Jovian flyby, the Ulysses spacecraft did not detect significant emissions in the 27-48 keV energy range [29] as would have been the case if electron bremsstrahlung was a major process. Observations of Jupiter x-ray's emissions by ROSAT [30] supported the suggestion of [25] and the model calculations [27,28] that precipitating energetic (>700 keV per nucleon) S and O ions are most probably responsible for the x-ray emissions from Jupiter. A detailed modeling of the x-ray production [31,32] suggests that recombination lines from highly charged precipitating O and S ions mainly contribute to the soft x-rays detected by ROSAT. Recent high-spatial resolution observations of Jupiter with the Chandra telescope [10] reveal that most of Jupiter's northern auroral x-rays come from a "hot spot" located significantly poleward of the latitudes connected to the inner magnetosphere. The hot spot is fixed in magnetic latitude and longitude and occurs in a region where anomalous infrared and ultraviolet emissions (the so called "flares") have also been observed. Its location must connect along magnetic field lines to regions in the Jovian magnetosphere well in excess of 30 Jovian radii from the planet, a region where there are insufficient S and O ions to account for the hot spot [10]. More surprising, the hot spot x-rays pulsate with an approximately 45-min period, similar to that reported for high-latitude radio and energetic electron bursts observed by near-Jupiter spacecraft. These results invalidate the idea that Jovian auroral x-ray emissions are mainly excited by steady precipitation of heavy energetic ions from the inner magnetosphere. Instead, the x-rays seem to result from currently unexplained processes in the outer magnetosphere that produce highly localized and highly variable emissions over an extremely wide range of wavelengths. In any case the power needed to produce the brightest ultraviolet "flares" seen in the same polar cap region as the x-ray hot spot is a few tens of TW, much less than the estimated power of a few PW needed to produce the observed x-rays by electron bremsstrahlung. Thus, electron bremsstrahlung still seems to fail in explaining the observed Jovian x-rays hot-spot. One possible source of Jovian x-rays production is via charge-exchange of solar wind ions that penetrate down the atmosphere in the magnetic cusp region. But in this case the solar wind ions would have to be accelerated to much higher energies (100s of keV), probably by parallel electric field or wave particle interactions, to generate sufficient luminosity to account for the observations. In summary, at the present time the origin of the Jovian x-rays and its source is still an open issue.

Non-Auroral Emissions
Soft x-ray emissions with brightnesses of about 0.01-0.2 Rayleighs were observed from the equatorial regions of Jupiter using the ROSAT/HRI. It was proposed [33] that the equatorial emission, like the auroral emission, may be largely due to the precipitation of energetic (>300

Fig. XI. CXO image of Jupiter on 18 December 2000. [from Ref. 10].
elemental abundances. Fluorescence would provide a direct measure of specific detection of weaker emissions due to L- and M-shell wavelengths. Although reflection of the strong solar lines determine the optical properties at visible and longer wavelengths. Other wavelengths. Other mechanisms should not be overlooked in the search for a complete explanation of low-latitude x-ray emission, namely elastic scattering of solar x-rays by atmospheric neutrals and fluorescent scattering of carbon K-shell x-rays from methane molecules located below the Jovian homopause. Modeled brightnesses agree, up to a factor of two, with the bulk of low-latitude ROSAT/PSPC measurements which suggests that solar photon scattering (≈90% elastic scattering) may act in conjunction with energetic heavy ion precipitation to generate Jovian nonauroral x-ray emission. Solar x-ray scattering mechanism is also suggested from the correlations of Jovian emissions with the FI0.7 solar flux and of the x-ray limb with the bright visible limb [34]. Jupiter was observed in December 2000 by Chandra HRC-I, from which disk-averaged emitted x-rays power of about 2 GW was estimated [10], but the coverage of the disk was still not adequate to show the limb brightening expected by solar photon-driven x-ray emission.

4. MOON

Though being the Earth’s nearest planetary body, the Moon has been relatively little studied at x-ray wavelengths. Other than the discovery observation by [4] using the ROSAT PSPC and a detection by Advanced Satellite for Cosmology and Astrophysics (ASCA) [35], most recent high-energy remote sensing of the Moon has been made at extreme- and far-ultraviolet wavelengths [e.g., 36,37,38]. However, as noted by [39], x-ray fluorescence studies could provide an excellent way to determine the elemental composition of the lunar surface by remote sensing, since the soft x-ray optical properties of the lunar surface should be dominated by elemental abundances (rather than mineral abundances, which determine the optical properties at visible and longer wavelengths). Although reflection of the strong solar lines likely dominates the soft x-ray spectrum of the Moon, the detection of weaker emissions due to L- and M-shell fluorescence would provide a direct measure of specific elemental abundances.

5. COMETS
X-ray emission from a comet was first discovered in 1996 with the ROSAT observations of comet Hyakutake [42]. Extreme ultraviolet (EUV) emission was also detected from this comet by the EUVE satellite [43]. Since the initial discovery of cometary X-ray emission, it has been shown that active comets are almost always EUV and X-ray sources [44]. A thorough review of this topic has just appeared [6], so only a brief summary is provided here.

The key observational features of cometary X-ray emission are now summarized. The X-ray emission is "very soft" with photon energies of a few hundred eV or less. High-resolution X-ray spectra of comets C/LINEAR 1999 S4 [5] and McNaught-Hartley (C/1999 T1) [45] have recently been measured by the CXO. Emission lines associated with highly charged ions (in particular, O6+) are evident in these spectra. A spectrum of comet Hyakutake from the EUVE satellite [46] also displays line emission. Cometary X-ray luminosities are quite large and tend to correlate with the gas production rate [e.g., 47]. The comet Hyakutake X-ray luminosity measured by ROSAT was about 1 GW. Cometary X-ray emission is spatially very extensive with observed emission out to radial distances from the cometary nucleus of 10^3-10^6 km [e.g., 5,42]. The emission is also time variable and has been shown to correlate with the solar wind flux [e.g., 48].

Several cometary X-ray emission mechanisms were proposed following the initial discovery. These include bremsstrahlung associated with solar wind electron collisions with cometary neutrals and ions, K-shell ionization of neutrals by electron impact, scattering of solar photons by cometary dust, and charge transfer of solar wind heavy ions with neutrals [cf. 6]. The SWCX mechanism [49] has gradually won favor. In this mechanism highly charged solar wind ions (e.g., O6+, O7+, C6+, Ne9+,...) undergo charge transfer collisions when they encounter cometary neutrals. The product ions are invariably left in highly excited states and emit EUV and soft X-ray photons. This mechanism is able to explain the luminosity, spatial distribution [50], time variability [48], and spectrum [5,45,51,52] of the X-ray emission.

6. VENUS

In January 2001 the CXO discovered soft X-ray emissions from Venus [7,8]. Observations were performed with the CXO's ACIS-I high-resolution imaging camera and with the LETG/ACIS-S high-resolution grating spectrometer. The X-ray emission originated on the sunlit hemisphere, exhibited noticeable limb brightening (when compared to visible disk), and consisted primarily of O-K-alpha at ~530 eV. The C-K-alpha line emission at ~280 eV was also detected, with marginal evidence for N-K-alpha emission at ~400 eV. The carbon emission might also include a 290 eV line from CO2 and CO.

The derived energy fluxes in the oxygen and carbon lines were \(-2 \times 10^{-14}\) erg cm\(^{-2}\) s\(^{-1}\) for O-K-alpha and \(-5 \times 10^{-14}\) erg cm\(^{-2}\) s\(^{-1}\) for C-K-alpha. The total power in Venusian X-rays was estimated to be 30-70 MW. The Chandra data also indicated possible time variability on a timescale of a few minutes.

7. GALILEAN SATELLITES

Recently the CXO has discovered X-ray emission from the Galilean satellites [9]. The CXO observations of the Jovian system were made on 25-26 November 1999 for 86.4 ks with the ACIS-S instrument and on 18 December 2000 for 36.0 ks with the HRC-I instruments. The time tagged nature of the CXO data makes it possible to correct for varying satellite motions, and with ACIS it is also possible to filter the data by energy for optimum sensitivity. During the ACIS-S observation, Io and Europa were detected with a high degree of confidence, and Ganymede at a lesser degree of confidence. Io was also detected with high confidence during the shorter HRC-I observation. Over the nominal energies of 300-1890 eV range detected by ACIS-S, the X-ray events show a clustering between 500 and 700 eV, probably dominated
by the oxygen K-alpha line at 525 eV. The nominal energies of the x-ray events cluster between 500 and 700 eV, suggestive of oxygen K-alpha line emission at 525 eV. The estimated energy fluxes at the telescope and power emitted are $4 \times 10^{-16}$ erg cm$^{-2}$ s$^{-1}$ and 2.0 MW for Io, and $3 \times 10^{-16}$ erg cm$^{-2}$ s$^{-1}$ and 1.5 MW for Europa. Ganymede was roughly a third as luminous as Io. Callisto was not detected in either set of data.

The most plausible emission mechanism is inner (K shell) ionization of the surface (and perhaps incoming magnetospheric) atoms followed by prompt x-ray emission. Oxygen should be the dominant emitting atom in either a silicate or SO$_2$ surface (Io) or in an icy one (the outer Galilean satellites). It is also the most common heavy ion in the magnetosphere. The extremely tenuous atmospheres of the satellites are transparent to x-ray photons with these energies, and also to much of the energy range of the incoming ions. However oxygen absorption of the 525 eV line is such that the x-rays must originate in the top ~10 microns of the surface in order to escape. Simple estimates suggest that excitation by incoming ions dominates over electrons and that the x-ray flux produced is sufficient to account for the observations. Detailed models are required for verifying this picture and also for predicting the strengths of K-alpha lines for elements other than oxygen, especially heavier ones such as Na, Mg, Al, Si, and S. Within this framework, it is in principle possible to constrain the surface composition of these moons from x-ray observations, but this requires greater sensitivity than provided by the Chandra observations. The detection of x-ray emission from the Galilean satellites thus provides a direct measure of the interactions of magnetosphere of Jupiter with the satellite surfaces.

8. IO PLASMA TORUS

The Io Plasma Torus (IPT) is known to emit at EUV energies and below [54,55,56], but it was a surprise when CXO discovered that it was also a soft x-ray source [9]. The Jovian system has so far been observed with Chandra using the ACIS-S high-spatial-resolution imaging camera, which also has modest energy resolution, for two Jovian rotations in November 1999, and using the HRC-I high-spatial-resolution camera, with essentially no energy resolution, for one rotation in December 2000. X-ray emission from the IPT is present in both observations. The ACIS-S spectrum was consistent with a steep power-law continuum (photon index 6.8) plus a gaussian line (complex) centered at ~569 eV, consistent with K-alpha emission from various charge species of oxygen. Essentially no x-rays were observed above this spectral feature, consistent with the steepness of the power-law continuum. The 250-1000 eV energy flux at the telescope aperture was $2.4 \times 10^{-14}$ erg cm$^{-2}$ s$^{-1}$, corresponding to a luminosity of 0.12 GW, and was approximately evenly divided between the dawn and dusk side of Jupiter. However, the line emission originated predominantly on the dawn side. During the ACIS-S observation, Io, Europa, and Ganymede were on the dawn side, while Callisto was on the dusk side. For the HRC-I observation, the x-ray emission was stronger on the dusk side, approximately twice that observed on the dawn side. During the HRC-I observation, Io, Europa, and Ganymede were on the dusk side, while Callisto was on the dawn side.
even during flares from the active Sun, charge-exchange processes, previously invoked to explain Jupiter's x-ray aurora [e.g., 2,31] and cometary x-ray emission [e.g., 6,49], and ion stripping by dust grains fail to account for the observed emission. Assuming bremsstrahlung emission of soft X-rays by non-thermal electrons in the few hundred to few thousand eV range, with a kappa, or generalized Lorentzian, distribution with a temperature of 10 eV and an index of $\kappa = 2.4$ [57], which is consistent with the in-situ Ulysses observations, [9] estimated an IPT soft x-ray luminosity of 0.03 GW. This falls short of but is a significant fraction of the observed luminosity of 0.12 GW.

9. MARS

There seems to be a tentative detection of Martian x-rays in the ROSAT data [58]. However, so far no x-ray emission has been unambiguously detected from Mars, but this situation is expected to change soon. Alike at Venus, absorption of solar x-rays in either the carbon or oxygen K-shells followed by fluorescent emission of x-rays is suggested as the dominant process of x-rays production on Mars [53]. The predicted total soft x-ray intensity is 0.15 R that corresponds to x-ray luminosity of about 2.5 MW [53], which exceed the x-ray luminosity expected from the solar wind charge exchange mechanism on Mars [59]. A simulated image of SWCX-produced x-ray emission at Mars [59] indicates that this emission has a very different spatial morphology than the fluorescent x-ray emission [53], and future observations must be able to distinguish between the two processes.

10. SATURN

(SATURN)

Saturn is expected to have a predominantly solar-driven elastic scattering component to its x-ray radiation, much like Jupiter (predominantly H2 scattering with a small CH4 component) with perhaps about a third as much integrated non-auroral power as Jupiter....

11. SUMMARY

Table 1 summaries our current knowledge of the x-ray emissions from the planetary bodies that have been observed to produce soft x-rays. The x-rays from solar system bodies are relatively too weak (< few GW) and are from a much cold ($T <10^3$ K) environment compared to the x-rays from stars and other cosmic bodies ($>1W, T >10^5$ K). Nonetheless, the studies of planetary x-rays help advance our understanding of basic plasma-neutral (in both gas and solid phase) interactions that are important within our solar system, and plausibly in the extra-solar planetary systems as well.
