ABSTRACT

It is shown that the commonly held view of a sharp Fe K edge must be modified if the decay pathways of the series of resonances converging to the K thresholds are adequately taken into account. These resonances display damped Lorentzian profiles of nearly constant widths that are smeared to impose continuity across the threshold. By modeling the effects of K damping on opacities, it is found that the broadening of the K edge grows with the ionization level of the plasma, and the appearance at high ionization of a localized absorption feature at 7.2 keV is identified as the K\beta unresolved transition array.

Subject headings: atomic processes—line formation—X-rays: spectroscopy

1. Introduction

Absorption and emission features arising from iron K-shell processes are observed in the majority of X-ray spectra, and are therefore of practical importance in high-energy astrophysics. This is primarily due to the iron cosmic abundance, but also to the relatively unconfused spectral region where they appear. Although the observational technology in X-ray astronomy is still evolving, many of these features are being resolved and exploited as plasma diagnostics. In this respect, they are naturally grouped according to their origin, i.e. bound-bound or bound-free ionic transitions, and much of the interpretation of the latter has

relied on atomic calculations (Verner & Yakovlev 1995; Berrington et al. 1997; Donnelly et al. 2000; Berrington & Ballance 2001) that predict a sharp increase of the photoabsorption cross section at the K-shell threshold. The purpose of this communication is to emphasize that this commonly held view is incorrect due to an oversimplified treatment of the decay pathways of the resonances converging to this limit, and that previous astrophysical inferences from K-edge structures should thus be revised.

2. Constancy of K damping

When a photon is sufficiently energetic to promote a K-shell electron to an excited Rydberg state, the latter decays through radiative and autoionization (Auger) transitions. Illustrating these processes in the relatively simple case of Ne-like Fe XVII, the photoexcited K-vacancy states

\[ h\nu + 1s^22s^22p^6 \rightarrow 1s2s^22p^6np \]  

have access to the following decay tree:

\[
\begin{align*}
1s2s^22p^6np & \xrightarrow{Kn} 1s^22s^22p^6 + h\nu_n \\
& \xrightarrow{Ka} 1s^22s^22p^5np + h\nu_a \\
& \xrightarrow{KLn} \left\{ 
1s^22s^22p^5 + e^- \\
1s^22s^6 + e^- 
\right\} \\
& \xrightarrow{KLL} \left\{ 
1s^22s^22p^4np + e^- \\
1s^22s^2p^5np + e^- \\
1s^22p^6np + e^- 
\right\}
\]

The radiative branches are controlled, as indicated in Eqs. (2-3), by the Ka (2p \rightarrow 1s) array at \( \lambda \approx 1.93 \) Å and the Kn (np \rightarrow 1s) of which the most salient is the Kβ \equiv K3 array at \( \lambda \approx 1.72 \) Å. Mendoza et al. (2002) have recently demonstrated that, for any K-vacancy fine-structure state in the Fe isonuclear sequence, the width ratio \( \Gamma(\beta) : \Gamma(\alpha) \lesssim 0.23 \).

Equation (4) contains the participator Auger (KLn) channels where the np outer electron is directly involved in the decay. By contrast, in the KLL channels (Eq. 5) the np Rydberg electron remains a spectator. It has also been demonstrated by Mendoza et al. (2002) that, for any Fe K-vacancy fine-structure state with a filled L shell, the total Ka and KLL widths are practically independent of both the principal quantum number \( n \geq 3 \) of the outer-electron configuration and the electron occupancy \( N > 9 \), and keep a ratio of \( \Gamma(KLL) : \Gamma(\alpha) \sim 1.5 \). These findings illustrate the application of Gauss's law at the
atomic scale as previously discussed by Manson et al. (1991) in the context of the inner-shell properties of Kr and Sn. Furthermore, Mendoza et al. have also determined that Auger decay is 94% dominated by the KLL channels in Fe XVII and by no less than 76% in Fe X. Furthermore, preliminary calculations in iron species with \( N > 17 \) indicate that the latter KLL branching ratio is not significantly reduced even though the stronger KLM and KMM branches become spectator processes. Since both the participator Kn and KLn widths decay with the effective quantum number as \( \sim (n^*)^{-3} \), the total widths of K-vacancy states within an isonuclear sequence are constant to a good approximation for \( n \to \infty \) for all members with \( N > 3 \). In line with the previous discussions by Gorczyca (2000) and Gorczyca & McLaughlin (2000), the width constancy of high-\( n \) K resonances within an isonuclear sequence for members with \( N > 3 \) produce distinct signatures on the threshold structures of their photoabsorption cross sections which have been measured in the laboratory in O I and Ne I but which have been seriously underestimated in many atomic calculations.

3. The Fe XVII case

In order to illustrate quantitatively the effect of Auger spectator resonances, we make use of the Breit–Pauli R-matrix (BPRM) method (Berrington et al. 1978) to study K damping in Fe XVII. This numerical approach is based on the close-coupling approximation whereby the wavefunctions for states of an \( N \)-electron target and a colliding electron are expanded in terms of a finite number of target eigenfunctions. As can be deduced from Eq. (5), BPRM calculations can handle spectator Auger channels only for low-\( n \) K resonances since the close-coupling expansion must explicitly include \( n \) target states. However, Gorczyca & Robicheaux (1999) have modified BPRM to implicitly account for the spectator Auger channels by means of an optical potential devised from multichannel quantum defect theory. A target-state energy now acquires the imaginary component

\[
E_i \rightarrow E_i - \text{i} \Gamma_i/2
\]

where \( \Gamma_i \) is its partial decay width. This treatment of spectator Auger decay is thus analogous to that of radiation damping (Robicheaux et al. 1995).

In order to discern the contributions of the KLL channels to the total Auger widths, several BPRM calculations are carried out for the Fe\(^{17+}\) + e\(^-\) system. Firstly, only target levels from the 1s\(^2\)2s\(^2\)2p\(^5\), 1s\(^2\)2s2p\(^6\), and 1s2s\(^2\)2p\(^6\) configurations are included in the expansion thus only accounting for participator Auger decay. In a second calculation, levels from the 1s\(^2\)2s\(^2\)2p\(^4\)np, 1s\(^2\)2s2p\(^5\)np, and 1s\(^2\)2p\(^6\)np configurations with \( n \leq 4 \) are added to the target representation which now maps out the complete Auger manifold for the 1s\(^{-1}\)3p and 1s\(^{-1}\)4p
resonances. In Table 1, the resulting Auger widths for these resonances are compared, where increases by KLL decay greater than an order of magnitude and constant total Auger widths are depicted.

In a further calculation, the BPRM plus optical potential approach of Gorczyca & Robicheaux (1999) is employed to study the effects of radiation and Auger damping on the resonance structure. Fig. 1 shows the photoabsorption cross section of the 1s2s2p6 2S1/2 ground state of Fe xvII in the near K-threshold region. It may be seen that the undamped cross section is populated by a double series (1s−1np 31P0) of narrow and asymmetric resonances that converge to a sharp K edge. The inclusion of radiation (Kα) and Auger (KLL) dampings leads to resonance series with constant widths and symmetric profiles that get progressively smeared with increasing n to produce a smooth transition through the K threshold; in low resolution, the edge would thus appear to be downshifted in energy. The symmetric profiles are, as discussed by Nayandin et al. (2001), a consequence of the fact that KLL and Kα channels give rise to continuum states that cannot be reached by direct photoionization of the ground state and thus cause the Fano q parameter to tend to infinity. Resonance smearing is the result of oscillator strength conservation which must enforce an approximate (n*)−3 reduction of the resonance peak-values due to their constant widths.

3.1. K-edge spectral signatures

An advantage of the simple behavior of K damping is that its impact on the opacities can be estimated with an analytic model. The latter has been established and validated with the BPRM photoabsorption cross section of Fe xvII: the damped 1s−13p resonances are fitted with Lorentzian profiles and extrapolated with n* assuming constant widths and intensities decreasing with (n*)−3, the resonance positions being deduced by the usual Ritz formula. The cross sections of all the other Fe ions in the near threshold region are then determined in a similar fashion assuming a single 1s → np Rydberg series of smeared resonances for each species with n ≥ 2 for 4 ≤ N ≤ 9, n ≥ 3 for 10 ≤ N ≤ 17, and n ≥ 4 for 18 ≤ N ≤ 26. Since the resonance widths can be assumed constant with n for N > 9 (Mendoza et al. 2002), they are assigned the value of the 3p resonances in Fe xvII, namely 4.5 × 10−2 Ryd. For N ≤ 9, this value is scaled by a factor of N(N − 1)/90. The resonance intensities of the first few members of each series are obtained from multiplet f-values computed with the atomic structure code HFR (Cowan 1981), and the K-threshold positions and background cross sections are taken from Verner & Yakovlev (1995).

The monochromatic opacities are generated with the XSTAR program (Kallman & Bautista 2001); the self-consistent ionization balance and electron temperature are com-
puted under the assumption that ionization and heating are primarily due to an external source of continuum photons and that all processes are in a steady state. Solar abundances and a $F_c \sim \epsilon^{-1}$ continuum power law are adopted. As shown in Fig. 2, results are characterized in terms of the familiar ionization parameter $\xi \equiv L/nR^2$ in the range $0.01 \leq \xi \leq 100$ where $L$ is the luminosity of the incident X-ray radiation, $n$ the gas density, and $R$ the distance from the radiation source. Two distinctive spectral signatures emerge: (i) the concept of a sharp edge only applies for low ionization ($\log_\epsilon \sim -2$) plasmas, and its progressive broadening is a function of ionization; (ii) for $\log_\epsilon > 0$, a strong absorption feature appears at the piedmont ($\sim 7.2$ keV) caused by the Kβ unresolved transition array (UTA).

4. Observations

Broad K-edge absorption structure have been widely observed in the X-ray spectra of active galactic nuclei and black-hole candidates as reviewed by Ebisawa et al. (1994), and references therein, and more recently reported by Done & Zycki (1999) and Miller et al. (2002). They have been interpreted in terms of the reflection of X-rays by optically thick accretion disks around central compact objects, partial absorption models, or relativistic smearing. Furthermore, an unidentified local absorption feature at $\sim 7$ keV just below a smeared K edge has been reported by Ebisawa et al. (1994) in the bright GS 1124–68 X-ray nova and by Pounds & Reeves (2002) in the MCG-6-30-15 Seyfert 1 galaxy; however, the fitted ionization parameter of $\xi \sim 5.9$ in the latter seems to support our predicted edge signatures. It is expected that the present findings will contribute to accurate spectral modeling above 7 keV which has recently been described as critical by Pounds & Reeves (2002). However, reliable quantitative modeling implies a revision of the inner-shell photoionization cross sections for the Fe isonuclear sequence which is currently underway.
