Received 29 September 2000 / Accepted

Abstract. The luminous infrared-loud quasar IRAS 13349+2438 was observed with the XMM-Newton Observatory as part of the Performance Verification program. The spectrum obtained by the Reflection Grating Spectrometer (RGS) exhibits broad \( FWHM \sim 1400 \text{ km s}^{-1} \) absorption lines from highly ionized elements including hydrogen- and helium-like carbon, nitrogen, oxygen, and neon, and several iron L-shell ions \( \text{Fe}^{xvii} \). Also shown in the spectrum is the first astrophysical detection of a broad absorption feature around \( \lambda = 16 - 17 \text{ Å} \) identified as an unresolved transition array (UTA) of \( 2p - 3d \) inner-shell absorption by iron M-shell ions in a much cooler medium; a feature that might be misidentified as an \( \text{O}^{vii} \) edge when observed with moderate resolution spectrometers. No absorption edges are clearly detected in the spectrum. We demonstrate that the RGS spectrum of IRAS 13349+2438 exhibits absorption lines from two distinct regions, one of which is tentatively associated with the medium that produces the optical/UV reddening.

Key words: atomic processes – line: formation – techniques: spectroscopic – quasars: absorption lines – quasars: individual: IRAS 13349+2438 – X-rays: galaxies

1. Introduction

IRAS 13349+2438 is an archetypal highly-polarized radio-quiet quasar at a redshift of \( z = 0.10764 \) (Kim et al. 1995). Since its identification as an infrared-luminous quasar (Beichman et al. 1986), this source has been extensively studied in the optical, infrared, and X-ray bands. In a detailed investigation of the optical and infrared spectra and polarization measurements, Wills et al. (1992) demonstrated that the nuclear spectrum exhibits two distinct components; a highly-reddened component and a highly-polarized component that suffers much lower extinction. Based on these observational facts, Wills (1992) constructed a simple and elegant picture of the nuclear region of IRAS 13349+2438 in which the direct AGN radiation is attenuated through a thick dusty torus, while the observed highly-polarized light is produced by scattering in an extended bipolar region, either by warm electrons or by small dust grains.

IRAS 13349+2438 was detected in the \textit{ROSAT} All-Sky-Survey (Walter & Fink 1993; Brinkmann & Siebert 1994), and has been the target of extended pointed observations with \textit{ROSAT} (Brandt, Fabian, & Pounds 1996), and with \textit{ASCA} (Brinkmann et al. 1996; Brandt et al. 1997). In general, the analyses of these data sets have suggested the presence of absorption edge features due to ionized species of oxygen \( \text{O}^{viii} \) and \( \text{O}^{vii} \), although, because of the low spectral-resolving-power capabilities of the available detectors on these missions, the precise nature of the soft X-ray spectrum has remained controversial. Siebert & Brinkmann (1999) self-consistently accounted for the effects of dust embedded in the warm absorbing medium, and concluded that single zone models, both with and without internal dust, do not provide adequate fits to the combined, \textit{ROSAT}, \textit{ASCA}, and optical data sets. In particular, they find that a dust-free warm absorber model formally gives the best fit to the X-ray data, and conclude that the X-ray absorption and optical reddening must arise in spatially distinct regions.

In this Letter, we present results from the first high-resolution X-ray observation of IRAS 13349+2438 with the XMM-Newton Observatory. The spectrum obtained with the Reflection Grating Spectrometer (RGS) shows a wealth of discrete spectral features, including the first
astrophysical detection of inner-shell 2p - 3d absorption by M-shell iron ions in the form of an unresolved transition array (UTA). From a detailed analysis of the rich absorption spectrum, we measure the column density and velocity field of the line-of-sight material. We show that the spectrum contains absorption features from regions with two distinct levels of ionization. The column density of the lower ionization component is consistent with the observed optical reddening, and we tentatively associate this component with the dusty torus.

2. Observation and Data Reduction

IRAS 13349+2438 was observed with the XMM-Newton observatory (Jansen et al. 2000) on 19 - 20 June, 2000 during the Performance Verification phase for a total exposure time of 42 ks. The data obtained with the RGS (den Herder et al. 2000) were filtered through standard event-selection criteria using the XMM-Newton Science Analysis Software (SAS). The source spectrum was extracted using both dispersion/cross-dispersion coordinates and dispersion/pulse-height coordinates, which include 90% of the source photons. The background spectrum was generated using all of the events that lie outside the spatial mask. Wavelengths were then assigned to the dispersion coordinates. The current wavelength scale is accurate to within ~ 8 mÅ across the entire RGS band of λ = 5 - 35 Å (E = 0.35 - 2.5 keV).

The European Photon Imaging Camera (EPIC; Turner et al. 2000) MOS1 data were also processed with the SAS. The MOS2 detector was operated in FAST UNCOMP mode, for which reduction by the SAS is not possible as yet. Source events were extracted using a circular region of radius 45". A nearby source-free region with a radius of 3' was used for the background. Three modes of the Optical Monitor (OM; Mason et al. 2000) were used during the observation. The V grism (or optical grism; exposure time 3000 s), UV grism (exposure time 1000 s), and the UVW2 filter (~ 1500 - 3000 Å; effective exposure time 6340 s). There is no significant variability in the UVW2 observations. Absolute flux calibrations for the grism data were not available at the time of writing. The optical spectrum shows clear evidence of Hβ emission but the signal-to-noise is insufficient to determine the presence of any other emission lines (within an observer frame wavelength range of ~ 3000 - 6000 Å). The UV spectrum (coverage ~ 2000 - 3500 Å) is too weak for spectral extraction.

3. Results of Spectral Fitting

3.1. Underlying Continuum Radiation

To first obtain a rough characterization of the shape of the continuum, we use the EPIC-PN spectrum, which has the highest statistical quality and covers a broad range in energy. The 0.2 - 10 keV spectral region can be well-fitted with a phenomenological model that consists of a power-law and two black body components absorbed through a Galactic column density of $N_H = 1.1 \times 10^{20}$ cm$^{-2}$ (Murphy et al. 1996). The EPIC-PN data require two black body components with temperatures of $kT \sim 70$ eV and ~ 12 eV. The best-fit powerlaw photon index of $\Gamma \sim 2.2$ is consistent with the value implied by the ASCA data (Brinkmann et al. 1996; Brandt et al. 1997).

The MOS1 data from 0.3 to 10 keV, excluding the 0.6 - 1.2 keV region where the RGS shows complex absorption features, were best-fit using a single blackbody plus power-law ($\chi^2$ of 1.59 for 199 degrees of freedom), which is generally consistent with the PN data. The blackbody temperature is $kT \sim 110$ eV. The best-fit photon index is $\Gamma = 2.1$ with a column density of $1.4 \times 10^{20}$ cm$^{-2}$, which is only slightly higher than the Galactic value of $1 \times 10^{20}$ cm$^{-2}$.

3.2. The Absorption Spectrum of IRAS 13349+2438

The RGS spectrum shown in Figure 1 exhibits numerous absorption lines from a wide range in levels of ionization. The most prominent features in the spectrum are K-shell absorption lines of H- and He-like carbon, nitrogen, oxygen, and neon, and L-shell lines of Fe XVII - XX. The spectrum also shows a broad absorption feature between $\lambda \sim 16 - 17$ Å ($E \sim 730 - 770$ eV). The observed location of the red "edge" of this feature is at $\lambda = 17.10 \pm 0.05$ Å in the rest-frame of the quasar, and is close but undoubtedly inconsistent with that of the O VII photoelectric edge ($\lambda = 16.78$ Å). The shape of the absorption trough towards the shorter wavelengths is also incompatible with that of a photoelectric edge. We identify this feature as a UTA of inner-shell 2p - 3d resonance absorption lines in relatively cool, M-shell iron. The shape of this feature is strikingly similar to laboratory absorption measurements.
of a heated iron foil (Chenais-Popovics et al. 2000), and also agrees well with our own calculations as described below.

We adopt a continuum model similar to that inferred from the EPIC-PN data; i.e., the sum of a powerlaw and a blackbody component, the latter merely in order to parametrize empirically the soft X-ray spectral shape. We also fix the powerlaw photon index to $\Gamma = 2.2$ and the column density of cold material to the Galactic value. With the continuum model defined, we then apply absorption components of H- and He-like C, N, O, and Ne, and Fe XVII - XXIV. Each ion is treated as a separate component in the spectral fit and contains all relevant resonance transitions from the ground-state and photoelectric absorption components of H- and He-like C, N, O, and Ne, and Fe XVII - XXIV. The line profiles are calculated accounting for thermal and turbulent velocity broadening. Transition wavelengths and oscillator strengths of the upper levels were calculated with the atomic physics package HULLAC (Bar-Shalom et al. 1998), except for the wavelengths of the strong Fe L resonance lines where we use laboratory measurement values described in Brown et al. (2000). We use photoionization cross sections from Verner et al. (1996). For the iron UTA absorption, photon impact processes involving L-shell to M-shell excitations in Fe V - XVI are computed. All of the transitions $2^1P^0 3^1P^0 - 2^1P^0 3^1P^0$ ($x = 1$ through 12) are taken into account, of which the 2p - 3d excitations are the most important. For the atomic structure, the most significant configuration mixings, which conserve the total angular momentum within the n = 3 shell (namely 3p$^2$ + 3s3d), are included. This approximation is expected to be adequate for analysing the presently observed unresolved absorption feature. A more detailed discussion of the UTA is presented in Behar, Sako, & Kahn (2000).

Each component is then fit for the ion column density simultaneously with the black body continuum parameters and the normalization of the powerlaw component. The best-fit black body temperature is $kT \sim 100$ eV with a flux in the 5 - 35 Å range of $4.0 \times 10^{-3}$ photons cm$^{-2}$ s$^{-1}$. The flux in the powerlaw component is $2.4 \times 10^{-3}$ photons cm$^{-2}$ s$^{-1}$ in the same wavelength range.

The observed widths of the absorption lines, as shown below, are much larger than both the instrument line spread function and the thermal broadening of a gas with $kT \sim 10$ eV, which is the expected temperature for a photoionized plasma at this level of ionization. With the current statistical quality of the RGS data, however, we are not able to constrain the turbulent velocities $v_{\text{turb}}$ of the individual ion components. We, therefore, assume a uniform mean turbulent velocity field, keeping in mind that each ion can, in principle, exist in regions of different turbulent velocities. The derived ion column densities, therefore, may be uncertain to some degree, as quantified in the following section.

![Fig. 2. Same as in Figure 1 with the best-fit model spectrum superimposed.](image)

We obtain a statistically acceptable fit to the RGS data with $\chi^2 = 1.07$ for 532 degrees of freedom. The continuum parameters inferred from the RGS data are also consistent with those derived from EPIC-PN and EPIC-MOS. The intrinsic isotropic luminosities in the 0.3 - 2 keV and 2 - 10 keV regions are $L_X \sim 2 \times 10^{44}$ erg s$^{-1}$ and $\sim 5 \times 10^{43}$ erg s$^{-1}$ (assuming $H_0 = 65$ km s$^{-1}$ Mpc$^{-1}$ and $q_0 = 0.5$), respectively, which are lower than both the ROSAT PSPC and ASCA values by a factor of $\sim 5$. The measured ion column densities are listed in Table 1. To illustrate the statistical significance of the various components, we also list the changes in $\chi^2$ when each of the components is removed from the model. The best-fit FWHM turbulent velocity is $v_{\text{turb}} = 1430^{+280}_{-360}$ km s$^{-1}$, which is much larger than the thermal velocity of a photoionized medium. We also find weak evidence of an average bulk outflow velocity shift with $v_{\text{shift}} = +200^{+170}_{-180}$ km s$^{-1}$, where positive velocity denotes a blueshift.

4. Implications of the Results of Spectral Fitting

For the measured ion column densities listed in Table 1, many of the strong absorption lines of neon and iron L ions are in the logarithmic region of the curves of growth, which indicates that the derived column densities are highly coupled with the assumed turbulent velocity. Those of K-shell carbon, nitrogen, and oxygen, and iron M-shell ions, however, are in the linear regime, and the derived column densities are not very sensitive to the turbulent velocity.

As shown in Table 1, the detections of absorption lines from Fe VII - XII and Fe XVII - XX are highly significant. The column densities of the intermediate charge states of Fe XIII - XVI, however, are consistent with zero. This indicates that the line-of-sight material consists of either a multi-phase gas in a single medium, or two (or more) spatially distinct regions. Motivated by this observational fact, we refit the spectrum using the same model, ex-
The increase in ° The turbulent velocities for
find that the low-ionization-parameter component is sig-
ities of all the ions were fixed relative to one another, we
Fe. Contrary to our previous fit where the bulk veloci-
component including N vii, O VIH, Ne Ix, Ne x, and L-shell
parameters component including
ionization-parameter component including
component is consistent with zero (V_turb,hish = --20+_ km s-_).
This implies that the low-ionization gas is being acceler-
region is not therally unstable, based on XSTAR cal-
region (2.0 ≤ log ξ ≤ 2.5) that we observe in the spec-
however, indicates that substantial amounts of material
lines as well. The lack of absorption from Fe xiii – xvi,
however, indicates that substantial amounts of material
with ionization parameters in the range 1 ≤ log ξ ≤ 2 are
not present along the line-of-sight. Whether this is related
to the global structure of the circumnuclear medium or a
mure coincidence from a superposition of physically dis-
known.

The absorption lines from H-like nitrogen and oxygen,
H- and He-like neon, and L-shell iron are produced in a
medium with 2.0 ≤ log ξ ≤ 2.5 and an equivalent hydrogen
column density of N_H ~ 1×10^22 cm^-2. For a normal dust-
to-gas ratio, the observed reddening of E(B – V) = 0.3
(Wills et al. 1992) corresponds to a hydrogen column den-
sity of N_H = 1.7 × 10^21 cm^-2 (Burstein & Heiles 1978).
This value is slightly lower than the total amount of X-
ray absorbing material observed in the present X-ray spec-
trum. Coincidentally, however, the derived column density
of the low-ξ component is very close to that of the optical
reddening, although, we cannot conclusively associate the
low-ξ X-ray absorber with the dusty torus. The column
density of the high-ξ component, on the other hand, is a
factor of ~ 5 higher.

An interesting point to note is that the 1 ≤ log ξ ≤ 2
region is not therally unstable, based on XSTAR cal-
culations described above. On the other hand, the high-ξ
region (2.0 ≤ log ξ ≤ 2.5) that we observe in the spec-
trum is therally unstable. However, complications such as
non-solar metal abundances and/or inaccurate ioniza-
tion and recombination rates may alter the shape of the
thermal stability curve significantly, and, hence, the tem-
perature ranges of the unstable regions (Hess, Kahn, &
Paerels 1997; Savin et al. 1999).

* The turbulent velocities for all of the ions are fixed to the
same value. We find a best-fit with v_turb = 1430 ± 300 km s^-1
FWHM.

The absorption spectrum of IRAS 13349+2438 is qualita-
tively similar to those obtained with the Chandra trans-
mission grating observations of the Seyfert 1 galaxies
NGC 5548 and NGC 3783, which show narrow reso-
nance absorption lines blue-shifted by several hundred
km s^-1. (Kaastra et al. 2000; Kaspi et al. 2000). The de-

ered ion column densities in these sources, as well as in
IRAS 13349+2438, are in the range N_h ~ 10^{16}–10^{17} cm^-2,
and are not high enough to produce observable absorption

edges.

Conceptually, the low-ionization component observed
in IRAS 13349+2438 is similar to the "lukewarm ab-
sorber" that explains both the observed optical and X-
ray attenuation in NGC 3227 (Kraemer et al. 2000).
The spectroscopic signatures, however, are very different.
In particular, for the column densities derived from the
IRAS 13349+2438 data, the absorption features are dom-
inated by discrete resonance line transitions, mainly in
He-like ions and M-shell iron, and not by photoelectric
edges as in the model of Kraemer et al. (2000).
As demonstrated in our detailed spectral analysis of IRAS 13349+2438, the UTA feature is potentially a powerful diagnostic tool for probing cool absorbing material using high-resolution X-ray observations. If the low-ionization component is indeed associated with the dusty torus as the derived column density suggests, this feature should be detectable in other AGNs where the line-of-sight is partially obscured by the torus.
