PREFACE

Potential users of PEMs need to be reminded that unlike the military system of producing robust high reliability microcircuits that are designed to perform acceptably in a variety of harsh environments, PEMs are primarily designed for use in benign environments where equipment is easily accessed for repair or replacement. The methods of analysis applied to military products to demonstrate high reliability, cannot always be applied to PEMs. This leaves the user to struggle in an attempt to characterize PEMs for two reasons:

1. Due to the major differences in design and construction, the standard test practices used to ensure that military devices are robust and have high reliability often cannot be applied to PEMs that have smaller operating temperature range, typically are more frail, and susceptible to moisture absorption. In contrast, high reliability military microcircuits usually utilize large robust high temperature packages that are hermetically sealed.

2. Unlike the military high reliability system, users of PEMs have little visibility into commercial manufacturer's proprietary design, materials, die traceability, production processes and procedures. There is no central authority that monitors PEM commercial product for quality, and there are no controls in place that can be imposed across all commercial manufacturers to provide confidence to high reliability users that a common acceptable level of quality exists for all PEMs manufacturers. Consequently, there is no guaranteed control over the type of reliability that is built into commercial product, and there is no guarantee that different lots from the same manufacturer are equally acceptable. And regarding application, there is no guarantee that commercial products intended for use in benign environments will provide acceptable performance and reliability in harsh space environments.

The qualification and screening processes contained in this document are intended to detect poor quality lots and screen out early random failures from use in space flight hardware. However, since it cannot be guaranteed that quality was designed and built into PEMs that are appropriate for space applications, users cannot screen in quality that may not exist. It needs to be understood that due to the variety of materials, processes and technologies used to design and produce PEMs, this test process may not accelerate and detect ALL failure mechanisms. While the tests herein will increase user confidence that PEMs with otherwise unknown reliability can be used in space environments, such testing may not guarantee the same level of reliability offered by military microcircuits. PEMs should only be used where due to performance needs, there are no alternatives in the military high reliability market, and projects are willing to accept higher risk.
1. NASA/GSFC PEMs POLICY

The use of Plastic Encapsulated Microcircuits (PEMs) is permitted on NASA Goddard Space Flight Center (GSFC) spaceflight applications, provided each use is thoroughly evaluated for thermal, mechanical, and radiation implications of the specific application and found to meet mission requirements. PEMs shall be selected for their functional advantage and availability, not for cost saving; the steps necessary to ensure reliability usually negate any initial apparent cost advantage. A PEM shall not be substituted for a form, fit and functional equivalent, high reliability, hermetic device in spaceflight applications.

Due to the rapid change in wafer-level designs typical of commercial parts and the unknown traceability between packaging lots and wafer lots, lot specific testing is required for PEMs, unless specifically excepted by the Mission Assurance Requirements (MAR) for the project. Lot specific qualification, screening, radiation hardness assurance analysis and/or testing, shall be consistent with the required reliability level as defined in the MAR.

Developers proposing to use PEMs shall address the following items in their Performance Assurance Implementation Plan: source selection (manufacturers and distributors), storage conditions for all stages of use, packing, shipping and handling, electrostatic discharge (ESD), screening and qualification testing, derating, radiation hardness assurance, test house selection and control, data collection and retention. Use of PEMs outside the manufacturer’s rated temperature range requires written approval from GSFC. Specifically, PEMs must be:

- stored under temperature controlled, clean conditions, protected from ESD and humidity,
- traceable to the branded manufacturer,
- procured from the manufacturer or their approved distributor,
- tested to verify compliance with the performance requirements of the application environment over the intended mission lifetime,
- tested using practices and facilities with demonstrated capabilities sufficient to handle and test the technologies involved.

Testing in accordance with 311-INST-001 shall be performed as necessary to qualify and screen the devices, in order to verify compliance with the application requirements and project risk level, defined in the program Mission Assurance Requirements (MAR). Radiation evaluation shall address all threats appropriate for the technology, application and environment, including Total Ionizing Dose (TID), Single Event Effects (SEE) and displacement damage. Existing radiation data can be used only with the review and approval of the project radiation specialist.
PEMs with manufacture dates older than 3 years before the time of installation shall not be used without GSFC approval. Derating of PEMs must be addressed with consideration of specific material, device construction, device characteristics and application requirements.

Use of PEMs with pure tin plated terminations requires special precautions to preclude failures caused by tin whiskers. GSFC approval of mitigation strategies is required.

Exceptions to testing required by 311-INST-001 may be permitted by GSFC on a case-by-case basis, where it can be demonstrated that either existing lot specific test data show acceptable results, or the use of high risk PEMs represents low risk of functional loss should the part fail. All rationale for such exceptions shall be documented.

NASA will use part performance data collected in accordance with this policy to evaluate the policy’s effectiveness and to develop recommendations for future improvements and streamlining.
2.0 PRODUCT ASSURANCE SYSTEM FOR PEMs

2.1 Scope

This document establishes a system of product assurance for PEMs in order to invoke the GSFC PEM policy. It is based partly on existing qualification system for military and aerospace components, experience accumulated by the parts engineering community, and practices or guidelines established by high-reliability electronics industry.

2.2 Product Assurance System

Purpose. The purpose of this product assurance system is to mitigate the risk of PEM usage, evaluate long-term reliability of the parts, and prevent failures. Commercial PEMs are primarily designed for benign environments and are considered as high-risk parts when used in space applications. For this reason, no PEMs are considered acceptable in high reliability applications “as is” without additional testing and analysis to assure adequate reliability and radiation tolerance.

Primary Elements of the Product Assurance System

- **Screening.** The purpose of screening is to detect and remove defective parts and reduce infant mortality failures. The screening process proactively evaluates the reliability of the lot.

- **Qualification.** The purpose of qualification testing is to ensure that no wear-out mechanisms would cause premature failures during the part storage, ground phase integration period, and spacecraft mission. The qualification process provides information regarding reliability of the design and the technology.

- **Radiation Hardness.** Radiation effects on the parts (Total Ionization Dose TID and Single Event Effects SEE) must be assessed on a lot specific basis according to the project requirements.

- **Destructive Physical Analysis (DPA).** The purpose of DPA is to determine whether the lot has any design, material, workmanship or process flaws that may not show up during screening and qualification tests and cause degradation or failures during hardware integration period and spacecraft mission lifetime. When obvious gross defects are revealed during DPA, it is usually an indication that manufacturer’s processes are out of control, and a replacement of the lot might be required. Therefore, it is recommended that DPA should be performed prior to screening and qualification of the lot. Anomalies revealed by DPA raise concerns regarding quality and reliability of the parts. These concerns may be further addressed by tailoring screening and qualification procedures or by performing additional design evaluation and testing of the parts (refer section 6).
A relationship between the major elements of the product assurance system (screening, qualification, and DPA) and reliability of the parts can be illustrated using a classic bathtub shape curve of the lifespan failure rate shown in Figure 1. The three elements of the system discussed have been widely used for high-reliability parts and remain the major means to provide high quality PEMs for space projects.

![Diagram of product assurance system](image)

Figure 1. Product Assurance system for PEMs and its relationship with reliability

### 2.3 Additional Evaluations.

Additional evaluations might be necessary to further mitigate risks associated with the use of PEMs. These assessments shall include:

**Design Evaluation.** Additional part and application specific evaluations performed beyond standard screening, qualification or DPA may be necessary. Refer to section 6 which describes capabilities of this element of the product assurance system.

**Manufacturer History.** The manufacturer’s history of ability to produce consistent reliability and quality should be reviewed (refer to section 9).

**Distributor.** Use of reputable distributors is essential to avoid procurement of counterfeit parts. Use of brokers is not recommended. Distributor compliance to PEMs handling and storage requirements should be assessed.

**Qualification by Flight History.** For all PEMs, qualification by flight history or similarity is not acceptable. Commercial PEM manufacturers are known to produce the same part number with die sourced from different wafer lots having different die revisions. The same part number may also be made by multiple production plants, processed according to requirements that vary between wafer and assembly plants. However, the history of parts’ application is important and allows addressing specific problems of design and technology of the parts revealed previously.
2.4 Requirements for PEMs by project risk Levels

Requirements for use of PEMs in GSFC projects are shown in Table 1 for different project risk levels defined in 311-INST-001.

Notes:

1/ PEMs qualified according to this document are intended for operation within the manufacturer's data sheet limits. Any uprating and use of PEMs outside the manufacturer's specified range, particularly the temperature limits, is not acceptable.
3.0 REQUIREMENTS FOR SCREENING

General. Screening is the only element of the product assurance system, which is applied to all flight parts by testing and inspecting every sample and proactively affecting reliability of the lot. Refer to tables 2 and 2a for screening requirements of PEMs for projects of different risk levels.

Handling. There are numerous data indicating that improper handling and testing of the parts can introduce more defects than are screened out. Therefore, extreme cautions should be taken during handling, storage and testing to reduce the possibility of electrostatic discharge (ESD), electrical overstress (EOS), contamination, and mechanical damage to the parts. This demands scrupulous attention to the practice and requirements of handling and storage of the flight parts. Guidelines and requirements for handling and storage of PEMs are described in Section 8 of this document. A typical test flow for screening of PEMs is shown in Figure 3.

Figure 3. A typical test flow for screening of PEMs.

Notes:

1/ General.

1.1/. Screening is performed on 100% of flight parts.

1.2/. Historically, only parts with a tight lot-specific controls imposed during manufacturing had been allowed for applications in Level I projects. Such a control is impossible for PEMs and the suggested screening procedures are not considered as a substitute for manufacturing control, but rather as a risk mitigation measures.
It is recommended to combine the incoming/out-coming visual inspections with the serialization and packaging to reduce handling and possible damage to the parts. Serialization should be performed in such a way to allow a topside C-SAM inspection. Flight parts should be handled and stored in a manner to prevent mechanical and ESD damage, contamination and moisture absorption (see Section 8). External visual exam for screening should focus on gross defects only.

To minimize handling, only a top view X-ray inspection is required. Focus to inspect for wire sweeping and obvious defects in the part. Depending on the results of the top view X-ray and/or part construction, a side view may be required.

**4/ Acoustic Microscopy (C-SAM)**

4.1/ **General.** Acoustic microscopy is performed to screen out defects at critical, die surface and wire-bond areas of the parts and for screening, except for power devices, is performed only at the topside. Refer to section 5, paragraph 5.3.3 for C-SAM procedure.

4.2/ **Coated Die.** Inspection of the die area on parts with polymer die coating is not required as the die coating has a low acoustic impedance that appears as a false delamination.

4.3/ **Power devices.** For power parts the bottom side inspection of die attachment is req’d.

4.4/ **Rejection criteria.**
- Any measurable amount of delamination between molding compound and die;
- Any delaminations and on the leads at wire bond areas;
- Delaminations extending more than 2/3 the length of internal part of the leads.

5/ **Electrical measurements:**

5.1/ **Excessive Rejects.** Excessive rejects during initial electrical measurements are a legitimate cause for lot replacement.

5.2/ **Special Testing.** In addition to parametric and functional measurements per data sheets, supplement and/or innovative testing techniques (e.g. IDDQ leakage currents, thermal impedance, output noise, etc.) can be used to select better quality parts from the lot (cherry pick) as flight candidates. These techniques should be certified and approved by Code 562.

6/ **Percent Defective Allowable**

6.1/ If most of the PDA failures occur during C-SAM inspection, additional evaluation of the thermal stability and mechanical integrity of the lot shall be performed.

6.2/ When excessive rejects (high Percent Defective Allowable, PDA) are experienced, the project decides whether a lot replacement or additional screening is needed

7/ **Burn-in (BI):**

7.1/ **General.** Burn-in is typically performed out of the parts’ operational temperature range and most manufacturers will not consider burn-in rejects as valid failures. Burn-in is a complex, product-specific test and if possible should be conducted by the manufacturer of the part. If a user performs this test, special care should be taken not to exceed maximum current, voltage and die temperature limits.
7.2/ **Burn In Temperature.** The BI temperature is a “stress” temperature used to precipitate failure of defective parts and is typically much higher than the operational temperature of the part, where the characteristics are guaranteed to remain within the data sheet limits. Most PEM manufacturers use temperatures in the range from 125 °C to 150 °C to periodically perform BI to monitor quality of their product. However, if the Parts Engineer is unable to justify the suitability of burn-in at 125°C, the burn-in ambient temperature shall be limited to the maximum operating temperature per the device specifications provided by the manufacturer.

7.3/ **Junction Temperature.** The junction temperature during BI testing should not exceed the absolute maximum rated junction temperature for the part.

7.4/ **Molding Material Glass Transition Temperature.** When the die temperature is close to, or exceeds the glass transition temperature (Tg) of the molding compound (MC), electrical and mechanical properties of MC may change significantly and new degradation mechanisms may cause failures of the part. For most molding compounds, Tg values exceed 140 - 150 °C, which gives a necessary temperature margin for 125 °C BI. Reliability of the PEMs, which are manufactured with low-Tg molding compounds (Tg < 120 °C), are difficult to assess and such parts are not recommended for space projects without additional extensive analysis and testing. Glass transition temperature measurements are recommended prior to BI if usage of low-Tg molding compound for the lot is suspected.

7.5/ **Protection.** In some parts the sensitivity of the input/output ESD protection circuits increases with temperature and these circuits can be turned on easily, at lower and/or shorter voltage spikes, than at room temperature. By this reason, special care should be taken to prevent possible power line transients during burn-in testing.

7.6/ Excessive proportion of the functional BI failures, even when the total number of failures is within the PDA limits, might be an indication of serious lot reliability problems. In these cases additional testing and analysis of the parts might be req'd.

7.7/ Steady-state burn-in is performed on all linear and mixed signal devices (see Table 2a for details on burn-in conditions). The duration of steady-state burn-in can be reduced 50% if the parts are to be subjected to dynamic burn-in testing.

7.8/ Dynamic burn in is not required for parts operating under steady-state conditions, e.g. voltage references (see Table 2a for details on burn-in conditions).

7.9/ Only one type of BI test, either static or dynamic, is required for level 2 and 3 parts.

7.10/ Under special circumstances, when it is technically and economically viable, alternative testing in-lieu of static and/or dynamic BI testing (for example, board-level burn-in that is difficult to assess at the piece part level) may be permitted. It is the responsibility of the project PE to document and submit a rationale for the technical feasibility and equivalency of the alternative testing to the project and GSFC code 562 for approval. **Board level burn-in shall not be routinely substituted for piece part burn-in as a convenience.**

**Notes:**

1/ Reference MIL-STD-883, Method 1015. Static and Dynamic burn-in shall be performed at maximum recommended operating supply voltage with $V_{in}$ and $R_L$ selected to assure that the junction temperature shall not exceed $T_{jmax}$ specified for the device type.

2/ See Table 2 for BI ambient temperature conditioning.

3/ These are typical recommended electrical parameters. Since electrical parameters are device dependent, refer to detail specifications for actual dc and ac parametric test conditions and limits.

4/ For digital devices, all DC parameters, functional tests, and switching tests shall be performed at 25°C, at minimum operating temperature and at maximum operating temperature.
   For linear devices, all DC parameters shall be tested at 25°C, at minimum operating temperature and at maximum operating temperature. All AC and switching tests shall be performed at 25°C.

5/ For Level 2 and Level 3 parts only one BI test, static or dynamic is required.
4.0 REQUIREMENTS FOR QUALIFICATION

Qualification of PEMs is performed to evaluate long-term reliability by accelerating potential degradation processes which might cause wear-out failures of the parts. The major areas of reliability concern for PEMs are:

1. Mechanical Failures due to mechanical stresses in the package (package level wear-out);
2. Contamination Failures caused by moisture and contamination in the molding compound or at the die surface;
3. Wear-Out Failures related to the degradation processes in the die (die level wear-out);
4. Radiation Effects Failures caused by die susceptibility to degradation caused by gamma-irradiation and high energy charged particles.

Solder Reflow Simulation and extended Temperature Cycling are intended to demonstrate susceptibility of the parts to thermal stresses. Surface mount technology (SMT) PEMs experience a high temperature shock during solder reflow processes. The reflow temperature exceeds maximum processing temperatures experienced by parts during the curing of molding compounds and the glass transition temperature of the plastic. This can cause significant mechanical stresses, resulting in observable or latent damage to the package and die.

Highly Accelerated Stress Testing (HAST) is used to detect moisture and contamination related susceptibility to failures.

High Temperature Operational Life (HTOL) testing is performed at high temperatures and maximum operation voltage and is intended to accelerate most of the die-related degradation processes.

A typical test flow for qualification of plastic encapsulated microcircuits is shown in Figure 4. Table 3 presents details of the GSFC requirements for the qualification of PEMs for projects of different reliability levels.
Figure 4. A typical Qualification Test flow for PEMs.

Notes on next page
Notes:

1/ All parts shall be selected from a screened lot.
   It is the responsibility of the project parts engineer to submit qualification test results to Code 562 for logging-in to the Code 562 PEM database.

2/ This step is not performed if results of the screening are available.

3/ Radiation hardness of the parts must be assessed on a lot specific basis according to the project requirements. So that analysis can be completed prior to screening and qualification, un-screened samples can be used for this test. Additional number of samples, depending on radiation requirements, shall be provided by project to perform this test.

4/ The junction temperature should not exceed the absolute maximum rated junction temperature for the part. If 125°C ambient causes the maximum rated junction temperature to be exceeded, the ambient temperature should be decreased appropriately.

5/ Temperature Cycling is performed after HTOL testing on the same samples. This test can be also performed on a separate group of parts if additional samples are provided (22, 22, and 10 samples for levels 1, 2, and 3 respectively).

6/ Failure analysis is performed on any failures during qualification tests to determine whether they are caused by lot-related defects, manufacturing process problems or by improper testing. If no failures are observed, a reduced DPA should be performed to ensure that no degradation of wire bonding, cratering, and no mechanical damage to glassivation and metallization systems occurred (for level 1 and 2 parts only).

7/ Moisture soak is performed as a part of preconditioning to mimic worst-case moisture absorption conditions of the PEM molding material, which could cause PEMs to be damaged during soldering to boards.

8/ Conditions of the Temperature Cycling, HAST, and High Temperature Life Testing (HTOL) can be tailored according to specifics of the device application per code 562 approval. Guidelines for application-tailored qualification testing of PEMs shall be developed by code 562.

9/ This C-SAM examination is performed to estimate mechanical damage to the part due to temperature cycling and reflow simulation (or resistance to soldering test) by comparing acoustic images with the baseline measurement results.
5.0 DESTRUCTIVE PHYSICAL ANALYSIS (DPA)

This section describes purpose, test flow, and procedures for Destructive Physical Analysis (DPA) of commercial Plastic Encapsulated Microcircuits (PEMs) and is intended to supplement GSFC-S-311-M-70. (Specification for Destructive Physical Analysis (DPA))

5.1 Purpose of DPA for PEMs

Destructive Physical Analysis (or Construction Analysis, CA) provides important information regarding design, workmanship and process defects related to a PEM manufacturer lot. This information can be used for tailoring of screening and qualification test plans to focus on specific areas of reliability concerns.

DPA for PEMs should focus on three major areas of concerns: integrity of the package, quality of assembly, and defects in the die. This analysis should also evaluate package and die-level homogeneity of the lot. For this purpose, samples for DPA should be selected randomly from different portions of the lot.

An important benefit of DPA is to provide for comparison analysis of design and technology, to identify product change, and to provide baseline data in the event of subsequent failures, application problems and to provide data for physics of failure analysis.

5.2 DPA Test Flow

A typical test flow for destructive physical analysis of PEMs is shown in Figure 5.
Notes:

1. Requirements for die-level examinations in PEMs are the same as the requirements for hermetic military- or space-graded parts.

2. It is the responsibility of the Parts Lab or project engineer (when DPA is performed by a GSFC contractor) to submit a DPA report to Code 562 for logging-in to the PEM database.
5.3 GSFC DPA Procedure

5.3.1 External Visual Examination

Inspect each sample (5 samples minimum) at 3X to 10X magnification. One photograph of one typical device showing all markings shall be taken. All anomalies shall be photo-documented. Failure criteria of MIL-STD-883E, Method 2009, “External visual” are applicable except paragraphs 3.3.1.b, 3.3.2.a, 3.3.3, 3.3.5.e, 3.3.5.g, 3.3.8. In addition, inspect for any evidence of lot dissimilarity and the following defects:

- package deformation (nonplanarity, warping, or bowing),
- foreign inclusions in the package, voids and cracks in the plastic encapsulant,
- deformed leads, peeling, blistering or corrosion of finishing,
- condition of external leads and plating,
- legibility and correctness of marking,
- Evaluate homogeneity of the lot (package level)

5.3.2 Radiography

The purpose of this examination is to detect internal defects of the package and to determine die and wire placement for future decapsulation. Inspect all submitted samples for the following defects:

- foreign objects and voids in the encapsulant,
- voids in the die attach material,
- misaligned leads,
- burrs on lead frame (inside the package),
- poor wire bond geometry (wires that deviate from a straight line from bond to external lead or have no arc from die bonding pad to lead),
- swept or broken wires,
- improper die placement.

Radiographs shall be taken of each device in two views 90 degrees apart (top and side views). MIL-STD-883E, Method 2012, “Radiography” is applicable.

NOTE: When real time radiography is used for screening, the dose rate that the equipment emits should be estimated. Certain types of radiography can expose microcircuits to unusually high dose rates, such that damage can be introduced to sensitive parts. The radiation effects group should be consulted as necessary.

5.3.3 Acoustic Microscopy (C-SAM)

All samples shall be subjected to Acoustic Micro-imaging analysis. The purpose of this examination is to nondestructively detect the following defects:

- delamination of the molding compound from the lead frame, die, or paddle (top side and bottom side separately);
- voids and cracks in molding compound;
- unbonded regions and voids in the die-attach material (if possible).
5.3.3.1 C-SAM Requirements. The C-SAM procedure for screening should comply with the following requirements:

- A clean bath and deionized water should be used during acoustic examinations of the flight parts.
- The test personnel shall be ESD certified to NASA-STD-8739.7 “ESD Control”.
- Depending on storage conditions of the parts, a 1-hour bake at 125 °C should be performed to remove moisture from the parts after immersion into the water bath of an acoustic microscope.

5.3.3.2 Package Examination Sites

Examination of the package for voids, cracks, and delaminations shall be performed on each sample at six areas:

1. interface between the die and molding compound (top view);
2. interface between the lead frame and molding compound (top view);
3. interface between the die paddle periphery and molding compound (top view);
4. die-to-paddle attachment interface (if possible);
5. interface between the die paddle and molding compound (back view);
6. interface between the lead frame and molding compound (back view).

Notes:

- Combined C-mode scans can be performed to investigate more than one area during one scanning run.
- A-scan data (wave form analysis) should be performed to verify any delaminations (if observed).
- Die-attach inspection shall be performed per MIL-STD 883E, Method 2030, “Ultrasonic inspection of die attach” for the parts with the die mounted onto a substrate or heat sink. This standard can also be applicable for other package types provided the resolution is adequate to detect voids in the attachment material.

5.3.3.3 C-SAM Examination Procedure

Package surface roughness, mold marks, stamped marking and surface defects create additional ultrasonic wave reflections that hinder analysis results. Packages with nonflat shapes may require milling or grinding before analysis.

- Remove labels from the area to be scanned. Note all mold marks or defects, which may affect the scan results.
- Place sample in deionized water bath with the top surface parallel to the scanning plane of the acoustic transducer. Sweep air bubbles away from the unit surface and from the bottom of the transducer head.
- Set the focus by maximizing the amplitude of the reflection from the die-molding compound interface and perform acoustic scanning.
- If the lead frame-molding compound interface was not in focus, reset the focus and perform scanning of this interface.
Refocus the transducer to the periphery of the die paddle-molding compound interface and repeat acoustic scanning.

Refocus the transducer to the die attachment (if possible) and repeat acoustic scanning. If the image is not sharp enough, try to view the area from the back side of the part.

Turn the part over, sweep air bubbles away from the unit, focus the transducer to the back side of the die paddle, and perform acoustic scanning.

Refocus the transducer to the lead frame-molding compound interface and repeat acoustic scanning.

Verify anomalies and/or delaminations (if observed) using A-scan analysis.

5.3.3.4 Evaluation Criteria

The following defects shall be considered as gross defects and the lot shall be rejected:

Note: A polished cross section may be required to verify if rejectable internal cracks or delaminations are suspected.

1. Cracks in plastic package intersecting bond wires.
2. Internal cracks extending from any lead finger to any other internal feature (lead finger, chip, die attach paddle) if the crack length is more than 0.5 of the corresponding distance.
3. Any cracks in the package extending to the surface.
4. Any void in the molding compound crossing a wire bond.
5. Complete lead finger delamination from the plastic at the wire bond area.
6. The following aspects shall be considered as reliability concerns and additional testing and screening of the lot might be necessary:
   I. Delamination of more than half of the backside of the interface between the paddle and molding compound.
   II. Delamination of the tie bar or lead area of more than 0.5 of its length.
   III. Delamination at the top of the die paddle of more than 0.5 of the periphery area.

5.3.4 Package level Cross-Sectioning

Two devices, or 40% of the DPA samples, whichever is larger, shall be subjected to this examination. The purposes of this examination is to evaluate:

- wire bonding (both, to the die and lead frame);
- die attachment for voiding and delamination;
- integrity of molding compound/lead frame interface;
- lead frame plating and external leads finishing;
- lead frame – MC interface to ensure that there is no direct way (along the leads) for moisture and contamination to reach the die.
Inspect the following areas of the package and die for defects:

- Defects and cracks in the package.
- Condition of die attachment.
- Lead frame/molding compound delamination.
- Condition of wire bonding at contact pads.
- Contact pad cratering.
- Condition of wire bonding at lead frame.

SEM examination and X-ray microanalysis at the package level cross section is performed optionally or to get more details of anomalies observed during optical examination. This examination shall be focused on the following areas:

- Intermetallic formation at wire bond/contact pad interface.
- Composition and structure of molding compound, lead frame, lead frame plating and finishing.
- Assembly/molding compound integrity.

5.3.4.1 Cross-Sectioning Procedure

Half of the samples shall be sectioned along the leads of one side of the package and half along the leads of the other side of the package. The planes shall cross the package in a mutually perpendicular fashion along the leads in the vicinity of the paddle edge, approximately in the middle of the die. Parts with the paddle tie bars shall be sectioned along the bars. For samples, different planes shall be selected that cross different wire bonds to the die and to the leads. If suitable, a sample can be divided in two parts before potting. Each plane of cross section shall be examined microscopically first at a low power (30X to 60X) magnification and then at a high power magnification (75X to 200X). Optical examination of the bonds inspection shall be performed at up to X1000 magnification. Pictures of all defective bonds and package faults as well as at least one picture of a typical bond, die attachment, and overall package layout should be taken.

5.3.4.2 Evaluation Criteria

The following defects shall be considered as gross defects and the lot shall be rejected:

1. Package cracks and delaminations;
   - any evidence of external cracks other than between the lead and plastic;
2. Bonding:
   - lifted and shifted bonds;
3. Molding compound:
   - voids and cracks in vicinity of bonding wires.
4. Pure tin (Sn) finishing of the leads.

The following aspects shall be considered as reliability concerns and additional testing and screening of the lot might be necessary:

1. Package cracks and delaminations;
   - any evidence of delamination or cracking of more than 0.5 of the lead or tie bar length;
2. Bonding:
   * abnormalities in intermetallic compound formation;
   * cratering.
3. Die attach: voiding of more than 50%.
4. Molding compound:
   * foreign intrusions;

5.3.5 Internal Visual Inspection

5.3.5.1 De-capsulation Techniques.

Description of different decapsulation techniques including Milling, Manual Wet Etching, Chemical Jet Etching or Plasma Etching can be viewed at (http://nepp.nasa.gov/DocUploads/E449EBC9-30F5-4400-9F4CD447CF85ED7E/61206_DPA%20for%20PEMs.pdf).

5.3.5.2 Verification of the Decapsulation Quality

a. Confirm acceptance of the specimen for further bonding examination. At least 25%, or 3 wire bonds, whichever is more, should meet the following criteria: be clean, have no damage, and be exposed more than approximately 2/3 of their length.

b. Confirm acceptance of the specimen for further glassivation integrity and SEM examinations. At least 75% of the die area should be clean and have no damage caused by deprocessing.

c. Record any defects induced by the decapsulation that might affect the DPA results.

5.3.5.3 Examination

The decapsulated device shall be examined microscopically, first at low power (30X to 60X) magnification and then at high power magnification (75X to 200X) to determine the existence of the die-level and assembly-level defects, to verify the die lot homogeneity, and quality of decapsulation.

Pictures of all defects as well as an overall internal view of the die and die marking should be presented in the report.

The purpose of this inspection is to evaluate:
   * Mechanical condition of die;
   * Condition of wire bonds;
   * Condition of glassivation.

When necessary to get more details on observed anomalies, SEM examination of wire bond and glassivation is performed to inspect for:
   * Anomalies with intermetallic growth at wire bonds.
   * Damage to glassivation.
5.3.5.4. Evaluation Criteria

Evaluation criteria per MIL-STD-883E, Method 2013, “Internal visual inspection for DPA” are applicable. No device shall be acceptable that exhibits the following defects:

- Glassivation pinholes, peeling or cracks (in particular those specific to filler particle-induced damage).
- Metallization voids, corrosion, peeling, or lifting.
- Wire bonds lifting, misplacement, and excessive deformation.

Additionally, die-level lot homogeneity shall be evaluated.

5.3.6 Bond Pull Test

Two devices, or 40% of the DPA samples, whichever is larger, shall be subjected to this examination. Each sample which met the requirements per 4.3.5.2. shall be subjected to a destructive bond pull test.

The purpose of this test is to evaluate:

- Bond strength.
- Contact pad metallization adherence.
- Cratering.

The wire bonds shall be pulled to destruction according to MIL-STD-883, Method 2011, “Bond strength (destructive bond pull test)”, Condition D.

Note: According to MIL-STD-883, Method 2011, the pull is applied by inserting a hook under the wire approximately in the center of the loop. Normally, decapsulation exposes approximately 75% of the loop (exposure of the wire-to-lead bond would weaken the bond strength due to chemical attack). The wire tension in which the pull force is not applied in the middle of the loop and part of the loop is buried in plastic and may differ by a factor of two from the values identified in MIL-STD-883. This means that the rejection criteria per MIL-STD-883, Method 2011 may not be applicable.

Typically, the ball neck is the weakest site of a wire bond (in particular, because it has been annealed during ball formation). If another site of the wire bond is found to be broken, the site could indicate a problem (especially in the case of a ball-lift). A wire bond strength test may be greatly influenced by the history of the sample. Thermocycling or storage of the sample under high temperature and humidity environments can cause deterioration of the wire bond strength. Enhanced degradation of the intermetallic region of the gold-aluminum wire bonding pad interface occurs in the presence of some flame retardants in epoxy molding compounds (such as those containing bromine or antimony). In some cases, to ensure an adequate quality of the part and its long term reliability, different types of accelerated tests are recommended before the sample is subjected to the wire pull test.

Data records. Results of the bond pull test shall be recorded in the DPA records.
5.3.7 Glassivation Layer Integrity

One sample, or 20% of the lot, whichever is larger, which met the requirements per 4.3.5.2. shall be subjected to a glassivation layer integrity test. This test is performed to evaluate cracks, voids, and pinholes in glassivation. This examination shall be performed per MIL-STD-883E, Method 2021, “Glassivation layer integrity”.

5.3.8 Assembly Examination using Scanning Electron Microscope (SEM)

The purpose of this examination is to verify quality of wire bonding and glassivation integrity. It is performed if optical inspection reveals anomalies that require further analysis. Pictures of worst-case defective bonds and glassivation defects should be presented in the final report.

1. Glassivation shall be examined for delamination, pinholes, and cracks possibly induced by the filler in molding compound or mechanical stresses in the package (which typically occur at the die corners).
2. Wire-to-die bonding shall be examined for the following defects:
   - cratering of the bond pad on the die;
   - bond liftoff;
   - wire bonds which are sheared from the die pads;
   - intermetallic compounds visible more than 0.1 mil beyond the ball attachment periphery.

5.3.9 Die Metallization Examination using Scanning Electron Microscope (SEM)

One sample, or 20% of the lot, whichever is larger, which passed the requirements of 5.3.5.2 (decapsulation quality) shall be subjected to this test. The purpose of this examination is to evaluate acceptability of the die interconnect metallization in accordance with MIL-STD-883, Method 2018 and, in particular, look for the following defects:
   - Metallization mechanical defects.
   - Metallization patterning and alignment.
   - Step coverage.

5.3.9.1 Die-Level Cross-Sectioning

SEM examination and X-ray microanalysis at the die-level cross section is performed optionally or when optical examination finds suspected defects. The purpose of this test is to evaluate:
   - Quality of planarization (if applicable).
   - Condition of vias or step coverage.
   - Verification of metallization and passivation systems.
   - Metallization defects.
   - Passivation defects.
If die cross-sectioning is necessary, the die shall be separated from the plastic package. This can be done in two ways: by etching away the paddle or by removing most of the molding compound around the paddle followed by heating the part to a temperature above the eutectic, or solder melting point.

NOTE: It is important to remove all polymer residues from the die before cross-sectioning to achieve good quality polishing. Acid absorbed in the polymer remnants can mix with water during polishing and cause corrosion of metallization.
6.0 EVALUATION ANALYSIS

DPA procedures described in Section 5.0 specify minimum requirements for destructive physical analysis of PEMs intended for space applications. In some cases additional research beyond normal screening or DPA examinations may be necessary. In-depth evaluation analysis of the design and materials used in PEMs, custom tailored to analyze the technology as applied to the application, may be necessary. A series of specially designed (by a PEM expert) tests and examinations may be undertaken to provide a better understanding of part characteristics, materials and reliability, as necessary. This can include additional destructive and non-destructive physical analysis as well as special electrical testing, mechanical or environmental stresses, and measurements of the parts.

The need for an evaluation analysis usually arises due to a part failure in the system level testing, insufficient manufacturer data, and/or due to general concerns about the reliability of the part in specific application conditions. Some examples of these concerns are: effect of reflow conditions on mechanical integrity and reliability of the part; probability of ESD or EOS failures in the part under certain stress conditions; effect of special environmental (e.g. vacuum) or electrical (e.g. switching transients) conditions on reliability, long-term storage at extreme temperatures, effect of the flame retardant used in molding compound on long term wire bond integrity, etc.

In some cases, to address special quality or reliability concerns, an extended set of examinations to characterize design and materials used in PEMs may be required. The following list of characteristics gives an example of data which can be required:

**Package-related characterization:**
- Physical dimensions;
- Weight.

**Lead-related characterization:**
- Solderability;
- Lead finishing materials (addressing tin whiskers problems);
- Mechanical integrity of leads.

**Molding compound-related characterization:**
- Outgassing
- Mechanical characteristics (Tg, CTE);
- Chemical characteristics: impurities (P, Cl, Br, Na), α-particle emission;
- Types of flame retardant;
- Moisture characteristics (moisture diffusion and hygroscopic expansion coefficients).

**Die-related characterization (materials and design):**
- Passivation;
- Interlayer dielectric system;
- Metallization system.
7.0 DERATING REQUIREMENTS

Reliability of microcircuits encapsulated in plastics significantly depends on temperature of the part and the level of electrical stress applied during operation. For different degradation mechanisms, an increase in operating voltages increases the failure rate either according to the power law or the exponential law. However, the most critical factor affecting reliability of the parts is the operating temperature, which exponentially accelerates most of the failures. Decreasing temperature and electrical stresses during operation, or derating the part, decreases the probability of failures. Derating can be defined as a method of stress reduction by reducing applied voltages, currents, operating frequency, and power to increase reliability of the part.

Derating is widely used for high-reliability military and space-grade applications. It is even more essential for commercial PEMs. This is partially due to the fact that the thermal resistance for many ceramic or metal packaged parts is much less than for the same style plastic packaged devices. Correspondingly, the operational temperature of the die in a plastic package at the same dissipation power level will be higher.

General derating requirements are listed in table 4. Taking a conservative approach, derating requirements for PEMs should be more stringent than the requirements for their high-reliability equivalents. In addition to the requirements in Table 4, derating specific to some PEMs may be required based on design and technology of the part intended for special application. All part specific derating shall be approved by the project and GSFC code 562.

8.0 HANDLING AND STORAGE REQUIREMENTS

Scope. This section describes general guidelines for safe handling of PEMs and assemblies containing PEMs. There are three major areas of concern that should be taken into account when handling and storing PEMs. All are valid up to the board-level testing.

Areas of Concern

1. **ESD Sensitivity.** Most of the PEMs intended for space applications are advanced low voltage, low-power microcircuits (e.g. precise linear devices, advanced memories, etc.) which are extremely sensitive to ESD damage. ESD controls to meet NASA-STD-8739 “Electrostatic Discharge Control” shall be in place.

2. **Delicate Piece Part Packages.** Many PEMs have tiny leads, which can be easily damaged or contaminated. This can result in poor soldering of the part during installation onto boards and cause failure in the event of mechanical stress applied to the leads during temperature excursions, mechanical shock or vibration.

3. **Moisture Absorption and Contamination.** Moisture and contamination can penetrate through plastic packages and cause degradation and failures during testing and screening of the parts, during solder reflow process, and during operation after integration into the system.

Handling and Storage. Detailed procedures for handling, storing, and maintenance of PEMs and assemblies are to be developed. The IPC/JEDEC standard J-STD-033 can be used when applicable as a guideline for safe handling and packing of PEMs regarding moisture sensitivity. The requirements should follow the entire ground-phase handling of the parts including piece part testing, storage prior to installation, and board/system-level testing and storage after installation and integration into the system.

Below are some additional guidelines for measures, which should be undertaken to avoid introduction of latent defects during testing, handling, and storing of the flight parts:

- Reduce handling by reducing the number of screening steps;
- Avoid contamination of the parts by reducing their exposure to humid environments and by using ESD-protective finger cots and ESD protective bags;
- Use qualified test labs. Periodically check their conformity to proper handling procedures. Ensure that only certified personnel handle flight parts;
- Taking a conservative approach, all parts with a moisture sensitivity level of less than 2 (per IPC/JEDEC J-STD-033) shall be handled as 2a-5a level parts;
- Leads damaged during handling or reformed after forming or damage might remain strained and have microcracks. These parts should be marked as such, and are not recommended for use.

Cleaning. Detailed procedures for post installation cleaning (defluxing) and handling of assemblies with installed PEMs can be found in IPC SC-60A “Post Solder Solvent Cleaning Handbook”. In developing a procedure for safe cleaning of assemblies containing PEMs, use of IPC-CH-65A “Guidelines for Cleaning of Printed Boards and Assemblies” is recommended.
9.0 INFORMATION FROM MANUFACTURERS

This section describes guidelines for acquiring information from the manufacturer of PEMs, which might be useful to assess quality of the parts.

Table 4 displays questions to be posed and manufacturer data available from the web sites, which would help to evaluate the ability of the manufacturer to produce parts with consistent quality and to provide acceptable customer support. The data are combined in four categories: general information about the part, part design and lifespan assessment, manufacturer assessment, and process assessment.

This information is of mutual interest for the parts engineering community and might be useful for different GSFC projects. For this reason, the project parts engineer should submit a spreadsheet in a standard format according to Table 5 to Code 562 for logging-in to the PEMs database.

Notes:

1/. AOQ is the proportion of parts that are outside the manufacturer specification limits. Currently the quality assurance system employed by the most established PEMs manufacturers guarantees minimum a 3-sigma level process. This means that AOQ = 2700 ppm or 0.27% of all shipped parts might have parameters out of the data sheet specification. In some cases this level of failures is below 0.1% and even less than 2 failures in $10^9$ parts for a 6-sigma manufacturer. However, the parts manufactured by a 6-sigma process have higher quality only when the parts are used and operate at relatively low temperatures. For example, a 6-sigma commercial product, when used in automotive applications, is considered a 3-sigma product.

2/. Cpk is a measure of how well the process fits within the specification limits. It relates process variations to the specification limits using a "natural tolerance", $3\sigma$ and is applicable only for normal distribution.

$Cpk = \frac{\min(HSL - \mu), (\mu - LSL)}{(3\sigma)}$, where HSL is the higher specification limit, LSL is the lower specification limit, $\mu$ is the mean value, $\sigma$ is the standard deviation. Larger Cpk values indicate lesser variations in the process and more consistent quality of the product.
Appendix A: BASIS FOR GSFC POLICY ON THE USE OF PLASTIC ENCAPSULATED MICROCIRCUITS (PEMs)

Prepared by GSFC PEMs Team

Discussion of Policy Content

Allowance of the Use of PEMs

Goddard Space Flight Center (GSFC) is adopting the policy to allow the use of Plastic Encapsulated Microcircuits (PEMs) in spaceflight applications, in order to have access to the latest technology advances, which are offered in PEMs and only rarely in hermetic high temperature packages. The use of PEMs in space applications can bring advantages to the application in terms of performance and part availability but thorough evaluation of the thermal, mechanical and radiation environment, together with qualification testing and screening, are generally required to ensure reliability.

Environmental Factors

In space environments, the advantages of PEMs are often accompanied by additional risks of failure. This is especially true in applications where PEMs encounter stresses (temperature extremes, vacuum conditions, radiation, etc.) outside the operating conditions for which they were designed. PEMs are typically designed to operate within two temperature ranges: -40°C to +85°C (industrial) or 0°C to +70°C (commercial) in contrast to military hermetic styles which are generally rated from -55°C to +125°C. The PEMs manufacturer designs, selects materials and tests parts to meet the needs of their primary customers (commercial high volume) and principal end use environments (industrial or commercial) NOT for high reliability, spaceflight. PEMs are generally intended for use in benign environments, where failure in service can be mitigated by replacement, maintainability or repairability.

The sheer variety of materials and fabrication techniques that may be used in making PEMs represent a number of application concerns and reliability risks in space environments. Often, these materials and manufacturing techniques have little or no spaceflight heritage.
Typical environmental concerns for spaceflight include:

- Optical components are at risk of contamination from outgassing of the molding material in vacuum environments.
- Molding materials have varying glass transition temperatures that can affect their maximum testing and use temperature.
- Molding material dimensional creepage with respect to temperature and time may place stress on internal bonds and wires.
- Thermal cycling can generate mechanical stresses on bonds, die paddles etc. as a result of Coefficient of Thermal Expansion (CTE) differences between materials.
- Molding material in PEMs is usually in contact with the die and may contain ions or be the source of secondary emissions that can influence radiation susceptibility of the die. These factors can result in PEMs packaged die having lower radiation tolerance than the same die, hermetically packaged.
- Operation outside the device’s nominal rated temperature range may result in rapid deterioration of package properties, weakening of bonds, mechanical overstressing of the die, etc.
- PEMs are all susceptible to moisture ingress and absorption but to varying degrees dependent on design, materials and processing. While not a risk for corrosion or other deterioration in space vacuum, moisture can promote corrosion during storage and ground level processing as well as “popcorn ing” during soldering, if strict moisture controls are not enacted.

Other, PEMs Specific Reliability And Application Issues

High volume PEMs parts have steadily decreasing time periods between their introduction and obsolescence. Various reports put the current time to obsolescence in the range of nine to eighteen months. Rapid obsolescence has a number of impacts for spaceflight applications. Reprocurement to cover shortfalls or test fallout may not occur before the parts are no longer available. Good experience on one project is not useful for another project with similar needs, if the parts are no longer available. Multiple spacecraft programs with builds spaced years apart, require a one time, multi spacecraft buy or may require different parts for successive spacecraft.

Not only is rapid obsolescence an issue but this has also led to corresponding reduction in designed operational life of the die design. Reports say that PEMs designers are now operating on as short as a five year life expectancy. Design compromises, such as reduced metallization and oxide layer thicknesses reduce costs but also reliability and life expectancy. It has been reported that mask changes can occur as frequently as once a month. Die shrink changes are known to have dramatically impacted radiation tolerance.
PEMs manufacturers generally utilize continuous improvement philosophies that result in frequent, unannounced changes to designs, materials and processes. While improving performance or cost for the target commercial applications, such changes can have unconsidered, negative impacts for space applications.

For high reliability products, MIL specifications define the assignment of lot date codes and the composition of the corresponding lot. There is no such recognized definition for a PEMs lot, it is up to the manufacturer and the needs of their intended market. This situation results in traceability and lot sample testing concerns for the spaceflight user. It has been reported that as many as five distinctly different dice of the same function have been found in a single PEMs “lot”. In addition, a single lot of PEMs can be processed in a number of die fabrication facilities, packaging and test houses throughout the world. PEMs of the same nominal device type but manufactured through different flows in different facilities can be intermixed and marked with the same lot identification.

Counterfeit parts are an increasing problem in the semiconductor market, particularly PEMs. Such parts have an identical or near identical appearance to genuine parts but are known to have substandard quality, reliability and performance. It is essential to evaluate each lot of parts and to use reputable distributors for PEMs, in order to reduce the risk of purchasing counterfeit parts.

Rationale for User Imposed Qualification Testing and Screening

PEMs are not governed by strict military standards that require inspection of the die for workmanship flaws and the performance of burn-in on each device to remove early random failures. In lieu of piece part testing, PEMs vendors typically employ various sample based techniques for calculating reliability. Testing may include proprietary testing regimes and employ unique rules governing sample sizes or the exclusion of failures from reliability calculations. These variations can make it difficult to compare PEM reliability data from vendor to vendor, let alone from PEM to hermetically sealed part.

For these reasons, it is not prudent to rely solely on unvalidated reliability data from PEM vendors. Screening of PEMs is essential before they are inserted into most flight hardware. The most important element in screening for reduced reliability risk for PEMs is burn-in.

Burn-in at the piece part level addresses infant mortality, which represents a significant problem for space applications, and provides some insight into lot reliability and quality. If burn-in at the parts level is not performed, these needs must be addressed by another test approach agreed to by the project, such as board level burn-in, or board/box level Environmental Stress Screening.
The argument that burn-in of PEMs should be avoided as it reduces the Total Ionizing Dose (TID) resistance of PEMs should be rejected unless solid evidence is produced to support the claim. Most studies have shown burn-in to have an impact of 500 Rads or less. To properly evaluate TID of burned-in parts, the TID test samples must be burned-in prior to testing.

Radiation Lot Acceptance Testing (RLAT) of PEMs should be performed independently of any data that may exist for equivalent or similar hermetically sealed devices, and should be performed under the direction of the project radiation specialist. This is necessary as market conditions may drive unannounced process changes, creating differences in radiation response. It may be possible to dispense with single-event qualification of the PEM if data exist for the hermetic device. However, because PEMs are passivated with nitride layers, which are known to be responsible for TID sensitivity to Pre-irradiation Elevated Thermal Stresses (PETS), TID characterization should always be independently performed.

Testing and Qualification

Testing and qualification of EEE parts for space applications are usually performed to requirements specific to the risk level desired for the application. Three risk levels are currently defined for NASA GSFC Projects. Risk Level One has the lowest inherent risk and is intended for critical applications such as single-string, single-point failure and mission essential functions. Risk Level Two has an increased risk and is intended for general-purpose spaceflight applications, although use in single-string and single-point failure applications may be permissible with Project approval. Risk Level Three has an unknown risk due to the lack of formalized reliability assessment, screening and qualification, and due to unreported and frequent changes in design, construction and materials. These inherent risk levels can be modified by additional testing such that Level 3 parts can be elevated to Level 2, and Level 2 to Level 2+. Upgrading to Level 1 is theoretically impossible due to lot specific controls imposed during Level 1 manufacturing that cannot be imposed once the part has been finished.

Testing of PEMs should be tailored to the application and based on such factors as manufacturer history, analysis of materials, flight history, technology maturity, application criticality and redundancy.

Basic Screening

Minimum additional testing for PEMs is established in GSFC 311-INST-001 for mission risk levels 1, 2 and 3. A flow chart of the evaluation process is shown in Appendix I of this document.
Basic process flow:

- External visual inspection for workmanship defects such as, bubbles or voids in the plastic package, separation of the package from the terminations, lead corrosion etc.
- Radiography and C-mode Scanning Acoustic Microscopy (CSAM) to inspect for swept bond wires, delaminations, voids, damaged or displaced die, mixed die sizes and shapes etc.
- Functional testing to ensure parts meet requirements over the full application range of temperature, power, frequency, voltage etc.
- Destructive Physical Analysis (DPA for PEMs) on samples from each lot to inspect for internal workmanship, bond pull, step coverage, die passivation, metallization voids, corrosion, contamination etc.
- Radiation testing on samples from each lot. Each lot needs to be characterized for Total Ionization Dose (TID), Single Event Effects (SEE) and Displacement Damage from charged particles.

Qualification

Qualification is required on a lot-by-lot basis unless objective evidence is provided that qualification data for a previous lot of the same or similar devices is applicable to the lot in question. When qualification testing is required, GSFC 311-INST-001 defines risk level specific requirements.

Typical qualification flows include:

- Operational life test to simulate performance under application conditions and duration; may also be used to estimate life failure rate.
- Highly Accelerated Stress Testing (HAST), subjects parts to high levels of temperature and humidity to accelerate destructive processes such as corrosion, delamination and die attachment failure, detectable by post-HAST Destructive Physical Analysis (DPA). Preconditioning of the samples that includes solder exposure, is recommended.

Additional Testing to Lower the Risk of PEMs

In addition to the basic process flow described previously, the following additional tests shall be performed as required by GSFC 311-INST-001 and as tailored to the PEM for its application, based on project requirements:

- Temperature Cycling to excite material CTE mismatches and stress wirebonds, die attachment etc.
- HAST or Temperature Humidity Bias to evaluate package integrity
- Burn-in for longer duration or at higher stress levels than the basic requirement
- Post test analysis consisting of PEMs specific DPA. CSAM may also be required.
Exceptions to Testing
Reductions to the testing listed in 311-INST-001 may be permitted with project approval on a case-by-case basis, where it can be demonstrated that:

- Existing test data for the delivered lot date code demonstrates acceptable results.
- Use of PEMs represents low risk of functional loss should the part fail. Low risk is defined as low application criticality or low potential for loss based on such things as:
  - light duty cycle
  - benign environment (minimal temperature extremes, radiation exposure, etc)
  - more than one redundant circuit
  - short mission life
  - and low mission cost.

All rationale for such exceptions must be documented.

Age Control

Due to molding material creepage, risk of corrosion, material aging etc., it is necessary to limit the age of PEMs to no more than three years from date of manufacture to date of installation, unless otherwise permitted by the project. Exceptions for age control may be granted by the project based on a need for the performance characteristics of older codes, or to use PEMs in inventory that are no longer in production.

Recommended Processing for Storage and Use of PEMs

- PEMs must be baked out prior to storage and prior to use in order to drive out absorbed moisture from the plastic molding material. Storage should be in dry environments (Nitrogen purged) at room temperature.
- The developer shall clean and dry boards using solvents and baking methods that will not risk compromising the reliability of parts or boards.
- The terminations of PEMs should be pretinned using tin-lead solder to reduce the risk of tin whisker growth or to remove gold plating. PEMs typically have pure tin plated terminations, which are a risk for tin whisker growth and subsequent system failure due to shorting or plasma arcs. Alternatively PEMs may be available with gold plated terminations, which are at risk for failure due to gold embrittlement.
- After installation and cleaning, the application of conformal coating to the devices is recommended to minimize re-absorption of moisture and to further reduce the risk of tin whisker growth.
Use of Off-the-Shelf Assemblies Containing PEMs

Use and function of off-the-shelf units or assemblies that contain PEMs should be analyzed for mission criticality. When loss of “off the shelf” units does not compromise mission success, on a case-by-case basis, these units may be considered exempt from additional PEMs testing requirements, subject to approval by the project. However, additional unit level testing such as thermal cycling or thermal vacuum testing, may be directed by the project in lieu of additional part level screening.

When failure of such units represents significant compromise to mission success, an analysis of the parts used within the units shall be performed. The parts shall be evaluated for screening compliance to GSFC 311-INST-001, and include a radiation analysis. Pending the results of this investigation, units may be required to undergo modification for use of higher reliability parts, additional shielding or replacement with radiation tolerant parts. When no high reliability parts are available, additional testing of the unit may be required. All parts upgrading or additional testing shall be subject to project approval.

If a “high-risk” designation is not acceptable for the application, then additional screening must be performed to ensure that the PEMs are consistent with a medium-risk or low-risk level as defined in the project MAR and GSFC 311-INST-001.

Appendix 1: PEM evaluation process

Start over w/ new part or adjust requirements

Initial Design PEM or Hermetic?

Is a functionally equivalent hermetic device available on schedule?

Yes

Use hermetic device w/ additional testing/screens, etc. as needed

No

Is high risk acceptable in this application? 1/

Yes

Use PEM that passes minimal screening and any additional required testing.

No

Is upscreens PEM acceptable in environment and application?

Yes

PEM must pass additional screening to establish it as moderate or low risk. 2/

No

Can part be repackaged hermetically and upscreens to low risk? Economically?

Yes

Use repackaged hermetically sealed device with any additional required testing (rad, etc.).

No

---

1/ High risk may be acceptable if the impact of part failure on achieving mission goals is minimal.

2/ Additional screening performed in accordance with GSFC 311-INST-001, or as project direction for the appropriate risk level.
APPENDIX B Product Assurance Methodology

Background. The Product Assurance methodology employed by PEM manufacturers is sufficient to meet most commercial user's needs. However, this system is significantly different compared to military and space-grade parts qualification systems used for providing high confidence in parts quality for high-reliability applications. These differences in approaches result in uncertainty in the reliability of PEMs, and require the end user to perform additional qualification, screening and analysis of the part to compensate for reduced testing by manufacturer.

General. The classic bathtub curve (see Figure 1, section 1) consists of three regions: infant mortality, useful life and wear-out. The infant mortality failures are induced by manufacturing defects and are related to shortcomings in the process control (quality failures). The wear-out failures are inherent to the processes used, materials and design of the part. For PEMs, these failures could be due to the die-related and package-related limitations. The first group of limitations is similar to the limitations of high reliability parts, e.g. time dependent dielectric breakdown (TDDB), electromigration, hot electron effects, and so on. The second group is specific to PEMs and could be due, for example, to corrosion of metallization in moisture environments, wire bond or die fracture during multiple temperature cycling and other package-related degradation mechanisms.

The infant mortality period, \( t_1 \), may last typically for a few months under normal operating conditions and is characterized by decreasing failure rate. The useful life period, \( t_2 \), lasts normally from 10 to 25+ years and varies significantly depending on the device technology, the level of stress during operation and on the wearout degradation process.

Manufacturers Methodology. Product Assurance methodology of most PEM manufacturers is based on the philosophy that the reliability must be designed or built into the manufacturing process rather than achieved by 100% testing of products. According to this methodology the emphasis is laid-on increasing the yield and reducing the likelihood of defective parts production by tight process control rather than on detection of failures during electrical testing. As a result, for many manufacturers outgoing screening of commercial PEMs usually consists of 100% external visual inspection, and room temperature functional and parametric electrical measurements. High temperature measurements are typically performed on a sample basis and allow a certain level of parametric failures. Quality and reliability data provided by most PEM manufacturers are mostly estimates based upon the history of performance of a group of parts manufactured by similar processes and encapsulated in similar packages. Design and manufacturing of commercial PEMs is mostly driven by a faster-
time-to-market demand and the product is often released without detailed qualification activities for economical reasons.

Goddard Space Flight Center, Code 562 Recommended Product Assurance system for PEMs is shown in Figure 2.

![Diagram of GSFC Product Assurance System for PEMs]

Every element of the Product Assurance system has its limitations and only a combination of all available means can provide cost-effective and comprehensive assessment of the quality of the parts and guarantee high reliability for space applications.

Creating and maintaining a database with the results of PEMs qualification and analysis performed for the Goddard Space Flight Center (GSFC) projects is an important element in the development of the knowledge-based system for quality assurance of PEMs. Reports with analysis and summary of the test results, as well as recommendations to improve the qualification system will be released annually by Code 562.
