Abstract. Engineering details are presented for a magnetized target fusion (MTF) propulsion system designed to support crewed missions to the outer solar system. Structural, thermal and radiation-management design details are presented. Propellant storage and supply options are also discussed and a propulsion system mass estimate is given.

INTRODUCTION

Magnetized Target Fusion (MTF) is a propulsion technique which combines features from both Inertial and Magnetic Confinement fusion approaches and capitalizes on research results in both areas (see Thio et al). The MTF technique offers the promise of both high specific impulse and low dry mass. As such it is well suited to the demands of high delta-v missions to the outer solar system, including human exploration. The work reported in this paper was carried out as part of the Human Outer Planet Exploration (HOPE) study, itself part of the Revolutionary Aerospace Concepts (RASC) program. The HOPE objective was to design a vehicle capable of conducting a human exploration mission of the Jovian moon Callisto. The MTF design, as reported here, was developed to satisfy the requirements of this mission.

This paper is organized as follows. First a brief overview is presented, addressing the basic processes involved in MTF operation. For the purposes of this description, the main fusion fuel is assumed to be deuterium. The subsequent sections are each devoted to an engineering description of a major component. Finally, the more advanced MTF system, using a mixture of deuterium and helium-3 as the main fusion fuel, is introduced and its principal differences from the basic system are explained.

BASIC MTF OPERATION

In outline, the MTF system operates as follows. A small plasma target of relatively easily-ignitable fuel (a 50% deuterium – 50% tritium molar mixture) is compressed to fusion conditions by converging streams of high-speed plasma, produced by an array of magnetoplasmadynamic (MPD) accelerators, also known as plasma guns. Energy released from the deuterium-tritium reactions in turn initiates fusion burn within a deuterium layer immediately surrounding the target. The use of a deuterium-tritium target, with its relatively low ignition temperature, makes the initial fusion burn relatively easy to initiate, but the main energy release comes from the deuterium-deuterium reactions in the surrounding layer. This minimizes the need for tritium, which is relatively
scarce and expensive. It also minimizes the number of high energy neutrons produced during fusion; those produced by the deuterium-deuterium reaction being of much lower energy than those created from deuterium-tritium fusion (2.45 MeV as opposed to 14.1 MeV).

The energy release during fusion produces a rapidly expanding hot plasma. By initiating the fusion event within the confines of a magnetic nozzle, part of the momentum of this expanding plasma cloud can be used to deflect and compress the magnetic field and thus exert a thrust on the vehicle.

The compression and fusion processes are illustrated conceptually in Figures 1 through 4.

Figure 1 shows a cross section through the plasma target with the various high-speed plasma streams converging on it.

![Converging Plasma Streams](image)

**FIGURE 1.** Plasma Streams Converging on Target Plasma
Figure 2 shows a single plasma stream in greater detail. The leading portion, exaggerated in the diagram for clarity, consists of deuterium plasma; the remainder consists of hydrogen plasma.

**FIGURE 2.** Detail of an Individual Plasma Stream

Figure 3a shows the target and surrounding liner, formed when the individual plasma streams coalesce. The inner and outer liners, composed respectively of deuterium and hydrogen plasma, are shown (again, the deuterium region is exaggerated in size). Figure 3b shows the point at which conditions in the target cause initiation of deuterium-tritium fusion. Figure 3c shows the point at which energy release from deuterium-tritium fusion in the target initiates deuterium-deuterium fusion in the inner portion of the liner.

**FIGURE 3.** Sequence of Events During Compression and Fusion

Finally, Figure 4 shows the hot plasma cloud expanding rapidly. Fusion reactions in both the central target region and the inner liner have now ceased.

**FIGURE 4.** Plasma Expansion Phase
Energy liberated during fusion, both in the target and the inner liner, appears in the form of particle kinetic energy. Charged particle energy is transferred into useful impulse by means of a magnetic field, formed by an array of current carrying coils, which is initially (at the moment of fusion) configured as shown in the left-hand part of Figure 5. As the plasma expands, the field lines are deformed, as shown in the right-hand part of Figure 5.

Distortion and compression of the magnetic field occurs because the plasma, being highly conductive, tends to strongly resist the incursion of any new magnetic flux.

The expanding plasma cloud's initial kinetic energy is transferred into potential energy in the compressed and deformed magnetic field. Note that the plasma expands freely through the (lower) open portion of the nozzle; no useful impulse is obtained from this part of the expansion.

When the plasma expansion ceases, the deformed and compressed magnetic field springs back towards its initial configuration, in the process expelling the remains of the cloud. During both the compression and expansion phases of magnetic field distortion, a very significant force is transferred to the vehicle, via the nozzle coils.

Electrical energy required to power the system's next pulse (i.e. to power the MPD accelerators and to create the initial magnetic field) is extracted during plasma expansion by a set of induction coils.

**TARGET GENERATION**

For a successful fusion burn, the deuterium-tritium target plasma must be located at the precise focus of the MTF nozzle; this is the point at which all the MPD accelerators are aimed. To overcome the problems of both creating and positioning the target, the following process is adopted. A pair of conical theta pinches, located in diametrically opposite positions on either side of the focus, is used to create and launch a pair of spheromak plasmoids towards the focus. The two spheromaks, which are identical in all respects except that their torroidal magnetic fields are oriented in opposite directions, collide and merge at the focus. It should be noted that, because of its minimum energy and self-generating magnetic field properties, the spheromak configuration has a relatively long life and will persist until the merging takes place. After merging is complete, the resulting plasma entity will be a Field Reverse Configuration (FRC) plasmoid.
Figure 6 shows a cross section through a spheromak plasmoid. Although there are both toroidal and poloidal magnetic fields, only the latter extend to the plasmoid surface.

![FIGURE 6. A Spheromak Plasmoid](image)

Figure 7 shows the two spheromaks approaching each other. They are identical in every way except that their toroidal magnetic fields are oriented opposite to each other.

![FIGURE 7. Two Spheromaks, with Opposing Helicity, About to Merge](image)
Finally, Figure 8 shows the single FRC plasmoid formed as a result of the two spheromaks having merged. Note that the toroidal magnetic fields of the parent spheromaks exactly cancel out, leaving a single plasmoid with solely poloidal field lines – an FRC.

\[ 
\text{FIGURE 8. Field Reverse Configuration Plasmoid Formed From Two Merged Spheromaks} 
\]

**PLASMA GUNS**

Shortly after FRC creation, the plasma streams arrive from the MPD accelerators and compression commences. It is clearly not possible to compress the FRC isotropically. The obvious requirement for a nozzle exit, to allow the fusion products to exit the MTF device, precludes mounting MPD accelerators in this region. With no plasma streams incident from below, any incident from above would have the effect of pushing the FRC out through the nozzle exit. As this is undesirable, there are no MPD devices located around the top of the nozzle. This leaves a band available, centered around an imaginary “equatorial” region of the nozzle, as illustrated in Figure 9.

\[ 
\text{FIGURE 9. Region of MTF Nozzle Available for Location of MPD Accelerators} 
\]

By locating the MPD accelerators within this “band” and ensuring that they are distributed symmetrically about the nozzle focus – which is the location of the target plasmoid at compression – one can ensure that there is no net momentum imparted to the FRC.
By restricting the MPD accelerator placement to within the allowable region, it is clear that the plasmoid will not be uniformly compressed over its entire surface by the converging plasma streams. Fortunately, this does not impede the compression dynamics. The FRC has the useful property that, when its periphery is compressed in one region, the resulting effect tends to shrink the magnetic field globally. As the magnetic field is "frozen" into the plasma, this means that the entire FRC is compressed. By arranging for plasma streams to impact the FRC in the region shown in Figure 9, one can ensure that the entire FRC is compressed.

The MPD accelerator is illustrated conceptually in Figure 10. The basic device consists of two concentric electrodes, which are connected to a high-energy capacitor. Gas is introduced into the annular gap between the electrodes and the switch is closed. This allows the capacitor to establish a high potential difference between the inner and outer electrode. The potential gradient between the electrodes causes breakdown and ionization of the gas. This completes the circuit and allows the capacitor to discharge.

The direction of current flow through the completed circuit gives rise to a self-generated magnetic field as illustrated in Figure 10. The field lines are oriented torroidally around the inner electrode. This self-generated field is everywhere perpendicular to the direction of current flow, which is, in this example, shown passing radially outwards from the inner to the outer electrode. This gives rise to a $\mathbf{J} \times \mathbf{B}$ force on the plasma (where $\mathbf{J}$ and $\mathbf{B}$ denote current density and magnetic field strength respectively), as shown in Figure 10, which forces it out of the device at high speed. Note that as the primary element of the plasma current is due to electron motion, it is the electrons which first experience the major part of the electromagnetic acceleration force. However, the very strong electrostatic forces, which are generated within the plasma as soon as any charge separation begins to occur, ensure that the ions are accelerated along with the electrons. The fact that it is a quasi-neutral plasma that is accelerated out of the device is significant in that it reduces concerns over the effect of space-charge limitations on the subsequent behavior of the plasma stream.

The actual design of the MPD accelerator is rendered slightly more complex by the need to focus the plasma stream and counteract the natural tendency to diverge on account of its inherent gas pressure. The solution to this problem is illustrated in Figure 11, which shows the accelerator portion of the device in greater detail and with greater realism than Figure 10. Each plasma gun is approximately one meter in length without the attached capacitor (1.4 m with the capacitor) and has a maximum barrel diameter of 0.25 meters. The barrel and capacitor are fitted together using a scyllac fitting to reduce impedance mismatch.
The converging two-barrel arrangement, with each barrel contoured internally, achieves the necessary focusing effect. Barrel shape must be such that the combination of electromagnetic and thermal expansion forces equal each other. This results in a nearly collimated high-speed gas flow.

The MTF plasma gun system consists of a total of forty-eight MPD accelerators, all positioned around the magnetic nozzle and directed towards its focus, as shown in Figure 12. The plasma guns are split into three banks. The upper bank, with twelve guns, is located above the focus. The middle bank, with twenty-four guns is level with the focus. The lowest bank, with twelve guns, is located below the focus.
Each plasma gun has its own individual capacitor to provide electrical power during discharge. Each plasma gun delivers a collimated plasma beam at a velocity of 125 km/s. As explained earlier, the small front portion of each beam consists of deuterium plasma; the remainder consists of hydrogen plasma. These high-speed beams converge onto the FRC and exchange their momentum to produce the extremely high power densities necessary for fusion.

Note that when the MPD Accelerators are discharged to produce the converging plasma streams aimed at the target, the nozzle magnetic field is not present. Only after the plasma streams are near to the target is the nozzle field initiated. This is to prevent the field from interfering with the plasma stream trajectories.

**MAGNETIC FIELD COILS**

The nozzle magnetic field performs two essential functions. First it acts as a shock absorber, taking the momentum of the expanding plasma cloud and transmitting it to the vehicle as a thrust force. Second, by slowing the expanding plasma cloud and then redirecting it back out of the nozzle, the magnetic field protects the structure and physical components of the nozzle from the extremely high plasma temperatures and from direct damage due to charged particle impacts. The current carrying coils, which are responsible for producing the major part of the magnetic field, are the primary nozzle components.

Eight single turn coils are placed in a parabolic arrangement around the nozzle. This configuration produces parabolic field lines whose focus coincides with the location of the fusion event. In order to close off the vertex of the magnetic field parabola, and prevent plasma from passing up along the axis, a single reversed conical theta pinch is installed at the vertex of the nozzle. Each of the eight coils, and the reversed conical theta pinch, is actually composed of two separate coil assemblies; an inner seed field coil and an outer thrust coil.

An applied current in the seed coils, immediately prior to the fusion event, produces the seed magnetic field. As the plasma cloud expands, post-fusion, it deflects and compresses the seed field — the highly conducting plasma closely approximates the frozen field-line model and thus resists incursion of the field. The plasma cloud expansion also induces very large currents in the outer thrust coils (also referred to as the main coils). These currents interact with the magnetic field, which strengthens as it is compressed by the expanding plasma cloud, to produce a very large J x B force on the main coils.

**Seed Coils**

Each seed field coil consists of a superconducting YBa2Cu3O7 single turn loop that is energized by a Superconducting Magnetic Energy Storage (SMES) system via a coaxially arranged superconducting power bus (of which further details are given later). The seed field coil is cooled with cryogenic liquid nitrogen, which flows through the conductor cable mesh. Superconducting coils were chosen to reduce the power loss due to ohmic heating. Once the seed field coils are energized, they produce the initial field within the nozzle.

**Main Coils**

Each thrust coil is coaxially laid over its associated seed field coil and, unlike the seed field coil, makes a continuous single turn loop. Because the thrust coil operates at high temperature, it is comprised of a thin layer of Titanium Diboride and Molybdenum (TiB2/Mo) metal matrix composite. This material has a conductivity comparable with that of copper, and a melting temperature exceeding 3000 K. The thickness of the conductor is set in order that the relatively slowly changing magnetic flux of the seed field coil can pass through it, but the more rapidly changing compressed flux is completely absorbed by the conductor. The thrust coil is responsible for commutating the compressed magnetic flux inside the nozzle and transforming it into thrust. This is accomplished by the Lorentz forces generated from the large magnetic field inside the nozzle and the very large (Mega-Amp level) currents induced in the thrust coils by the compressed magnetic flux.
Coil Structural Design

Between the large oscillatory impulses of the fusion events and the magnetic hoop stresses in the coils, the nozzle must withstand high dynamic loading conditions. Most of these forces are coupled to the structure through the magnetic coils. As a result, the coils must be structurally robust. This requirement along with the dielectric and thermal requirements of the coils makes material selection difficult. To solve these issues, advanced composites and ceramics must be used. Their superior strength, dielectric properties, and high melting temperatures allow for strong lightweight components. Also, because they can be laid up together, their use should reduce the need for complex machining.

Ceramics, however, are extremely brittle and do not withstand significant dynamic loading. Although they show exceptional strength against compressive loads, they have very low tensile strength. For this reason, it is important to lay-up these materials in such a manner that the loads can be transferred to an outer carbon-carbon composite that does have excellent tensile strength. A typical coil cross-section is shown in Figure 13 and its corresponding dimensions given in Table 1. These dimensions are based on a 2.488 Gigawatt mean jet power design for the MTF device.

A typical coil cross-section is described as follows — referring to Figure 13. Starting at the center of the coil assembly is the seed field coil conductor. This is a mesh of super conducting material, using a 3:1 conductor to coolant gap ratio. This allows adequate cryogenic coolant to flow along the conductor and still remain below its critical temperature. A layer of Kapton dielectric material surrounds the conducting mesh. This material serves as an electrical insulator and prevents arcing within the coil. The current through the seed field coil will cause it to undergo large hoop stresses due to the magnetic pressure within the loop. Because the current is pulsed, the seed coil will undergo a large number of stress cycles. A layer of carbon-carbon composite is wrapped around the thin layer of Kapton to prevent strain on the seed field coil. Outside the carbon composite are five 1 mm thick layers of low emissivity polished aluminum each separated by 0.8 mm thick evacuated areas. These alternating layers serve as a radiant energy heat shield and prevent heat from the thrust coil from sinking into the seed field coil. The coaxially layered aluminum layers are electrically continuous so that no net current can be commutated into them by the varying seed field flux. This assembly is covered with a thin layer of boron nitride to serve as a lightweight high temperature casing.

The thrust coil assembly surrounds the seed field assembly. These two assemblies are separated by an evacuated section 0.5 cm in thickness. This further reduces heat conduction from the high temperature thrust coil into the cryogenic seed field coil. Beyond this evacuated area is the structural carbon-carbon composite support for the thrust coil assembly. Loads from the thrust coil conductor are transferred into this support and into the nozzle as thrust. Both the thrust and seed field coils are structurally tied to the main support splines of the magnetic nozzle. The thrust coil conductor forms a “C” shape when viewed in cross section; the convex part of the “C” pointing towards the central axis of the nozzle. Since there is no magnetic flux compression outside the MTF nozzle, there is no need for a conductor on the outer side (i.e. furthest from the nozzle central axis) of the coil assembly. The high temperature TiB$_2$/Mo thrust coil conductor is completely surrounded by a layer of boron nitride. In addition to being a high temperature ceramic, boron nitride has excellent dielectric properties and can prevent arcing from within the coil.

To complete the thrust coil assembly, a molten salt coolant jacket is placed between the thrust coil conductor and the focus of the nozzle. This coolant jacket is made from zirconium diboride (ZrB$_2$), a high temperature ceramic that is not prone to reaction with the molten salt coolant. This will be further discussed in the cooling system section.

**MAGNETIC NOZZLE STRUCTURE**

As shown in Figure 14, the coil assemblies, target generators and plasma guns are all mounted on a structural framework, which serves to hold the various components in their correct location and also transmits the thrust force to the remainder of the vehicle. The structure consists of twelve equally spaced, tapered splines, each of which extends from very near the apex of the device down to some distance below the focus. In keeping with the nozzle profile, each spline has a near-parabolic profile. The structure is completed by four rings, as shown in Figure 12. It is envisioned that both the splines and the rings will be constructed of a carbon-carbon composite.
The deuterium-tritium fusion reaction, which takes place in the target plasmoid, can be written as follows (from Bond et al)

\[ _2^2\text{D} + _3^3\text{T} \rightarrow _4^4\text{He}(3.5 \text{ MeV}) + _1^1\text{n}(14.1 \text{ MeV}) \]

where \( _2^2\text{D} \), \( _3^3\text{T} \) and \( _4^4\text{He} \) denote deuterium, tritium and helium-4 nuclei respectively, and \( _1^1\text{n} \) denotes a neutron. The reaction product energies are indicated in parenthesis.

The deuterium-deuterium fusion, which takes place in the inner portion of the plasma liner, can proceed according to two different reactions, which can be written as follows (from Bond et al)

\[ _2^2\text{D} + _2^2\text{D} \rightarrow _3^3\text{T}(1.01 \text{ MeV}) + _1^1\text{p}(3.02 \text{ MeV}) \]
\[ _2^2\text{D} + _2^2\text{D} \rightarrow _3^3\text{He}(0.82 \text{ MeV}) + _1^1\text{n}(2.45 \text{ MeV}) \]

where \( _1^1\text{p} \) and \( _3^3\text{He} \) denote a proton and a helium-3 nucleus respectively.

The charged particle products of both the central and liner reactions can be deflected by the nozzle magnetic field and thus impart useful impulse to the vehicle without physical contact. However the neutrons, from both the core deuterium-tritium and the liner deuterium-deuterium reactions, being electrically neutral, cannot be
deflected. Despite the relatively open design of the nozzle lattice, which permits a significant proportion of the neutrons to escape, those which do still impact present one of the principal design challenges for an MTF propulsion system.

The challenge manifests itself in several ways. First it is necessary to protect the nozzle (including the structure, coils, plasma guns and other components) from the physical damage which would otherwise result from high-energy neutron bombardment. Secondly there is some induced radioactivity in the MTF structure. This can arise because slow neutrons, upon striking the nozzle, may be absorbed by the nuclei of those atoms which compose the structure, thus rendering them radioactive. Thirdly, as the neutrons, particularly those originating from the central deuterium-tritium reactions, have very high energies, they deposit a significant amount of thermal energy into the nozzle when they impact. Removing this very large heat flux, and limiting the nozzle material temperatures in order to maintain mechanical properties, are major challenges.

In mitigation, we note that a significant degree of neutron moderation may take place in the outer regions of the plasmoid. Immediately following fusion, when the thermonuclear neutrons are traveling outwards from the central regions, the density of the surrounding layers of compressed hydrogen will be very great. It is likely that a significant amount of neutron moderation will take place within this region due in part to the high density and in part to the excellent moderating capabilities of hydrogen, the dominant nucleus present. A full analysis of this process has yet to be conducted. Accordingly a somewhat pessimistic assumption of only 20% moderation has been made for the purposes of the HOPE design study. At some later stage, when the necessary moderation analysis has been conducted, it should be possible to favorably revise the MTF design. Both neutron shielding and thermal control system masses should decrease notably.

Neutrons can cause damage to materials in a variety of ways. Their total integrated flux, which is defined as the fluence, must be limited to prevent damage. High-energy neutrons normally pass through most materials without any atomic collisions simply because of the relatively large empty space that matter occupies. However, a certain percentage of these neutrons do collide with the nuclei of the atoms in the material. This type of interaction can result in atomic displacements, where the atom is driven out of its location within the crystal matrix. This phenomenon is referred to as neutron embrittlement and can be thought of as a microscopic strain hardening mechanism. If a large enough number of these events occur, as is the case in high radiation environments, the material will lose many of its structural, electrical, and heat conduction properties. Structural elements can fail, heat exchangers can lose performance, and electrical conductors can increase in resistivity. Without appropriate protective steps, all of these reactions would result in a decrease in the performance of the MTF propulsion system if not catastrophic failure.

Low energy neutrons can also produce adverse effects. Neutrons at low energies are more easily absorbed by atomic nuclei, usually resulting in the creation of a radioactive isotope. This too can change material properties and can cause serious problems with electronic circuitry. Fortunately for most materials there exists a range of energies at which the neutrons are too energetic to be absorbed, but at low enough energy to pass through without interacting with the nuclei. Within this energy range, the material is effectively transparent to the neutrons.

A neutron radiation shield capable of moderating neutrons with a range of initial energies would be a difficult design task. It would require that a composite shield consisting of many different layers of materials be used, with the outer layers slowing down fast neutrons, but allow slower ones to pass to the next layer. Each successive layer would have to repeat this until all of the neutrons were moderated to the appropriate energy. Such a shield would act as a neutron “filter” and would require much less mass than conventional shielding. Unfortunately, the design of such a “tailored” shield was not possible within the scope of the present study. With available techniques, at best, a large population of the high-energy neutrons can be reduced to a level of transparency. The fusion community is currently experimenting with the molten salt FLiBe (a mixture of Lithium Fluoride and Beryllium Fluoride, pronounced “flibe”). FLiBe has a good atomic cross section for slowing neutrons, a high vaporization temperature, and acceptable viscosity.
In addition to its shielding properties, liquid FLiBe can also serve as a primary cooling fluid. This yields a particularly efficient design solution as the material into which the neutron thermal energy is first deposited (the FLiBe) is also the medium which carries it away from the nozzle. The neutron energy must be pumped out of the system so that a nozzle operating temperature of no greater than 1,500 K is maintained. This is in keeping with the maximum operating temperature that the hottest portions of the nozzle can withstand. It also ensures that the FLiBe remains below its vaporization point.

For these reasons, FLiBe was selected as the neutron shield material and active cooling fluid for the MTF nozzle.

**MAIN COOLING SYSTEM**

At the focus of the MTF nozzle, the fusion reactions can produce plasma temperatures as high as 300 million Kelvin (the approximate temperature at which deuterium-deuterium fusion occurs). Fortunately, the plasma expansion process and the magnetic fields within the nozzle prevent material at these high temperatures from coming into contact with the structure. These mechanisms, however, do not prevent radiant electromagnetic (Bremsstrahlung) and neutronic radiation from reaching the nozzle structure. If left uncooled, the nozzle would quickly exceed its maximum allowable operating temperature and would melt, primarily on account of the neutron energy. Therefore an active cooling system is needed to remove the large (multi-Megawatt) heat input to the structure.

The resulting cooling system is a complex network of coolant channels running throughout the MTF nozzle structure and the coils. A variety of high temperature liquid metal and molten salt coolants flow within these channels. These coolants ultimately transfer the heat away from the MTF device and out to a radiator array for (radiative) disposal into space.

As explained earlier, due to the unique nature of the heating mechanism associated with gamma and neutronic radiation, the coolant must serve two purposes. It must not only carry away heat at a high temperature while remaining a liquid, but it must also serve as a radiation shield for the nozzle structure. Gamma radiation, when absorbed by a material, simply produces an increase in temperature. Although the heat from the gamma rays must be removed, it causes little damage when compared to that of the neutrons.

FLiBe flows down each of the twelve structural splines (see Figure 14) of the MTF nozzle along cooling channels below the surface facing the nozzle focus; it returns along a manifold located on the backside of the spline. FLiBe channels are also placed along the sides of each spline to serve as feed and return manifolds for the cooling channels placed along the structural ring stiffeners and the magnetic coils between each spline. FLiBe flows down the feed manifold on the right side of a spline. This manifold feeds eight coil coolant channels and three ring stiffeners coolant channels. All of these feed into the return manifold found on the left side of the adjacent spline. This splits the MTF nozzle into twelve different main circuits. All of these are combined into a common, structurally integrated feed and return manifold found at the interface of the MTF nozzle and vehicle.

High temperature FLiBe leaves the MTF nozzle along the common return manifold and feeds into a heat exchanger. This heat exchanger is part of a Brayton power cycle that uses helium as its working fluid. This Brayton system converts some of the heat of the MTF nozzle into mechanical energy by using a gas turbine that drives the power cycle compressor, FLiBe pump, and the cryocooler used with the SMES system. The remaining waste heat is sent to a radiator via a potassium-sodium working fluid heat exchanger. The cooled FLiBe is sent to the FLiBe pump and returned to the MTF nozzle along the common feed manifold.

The Brayton power cycle heat exchanger also serves an additional function. Since the MTF propulsion system must be shutdown during various phases of the mission (e.g. while at the destination), the heat source that normally keeps the molten FLiBe a liquid will be absent. From an operations perspective, it is undesirable to
allow the FLiBe to solidify. The HOPE vehicle utilizes an SP-100 fission reactor to provide non-propulsive
power for mission operations. This is a 375-megawatt electrical (2 megawatt thermal) output reactor that uses a
liquid metal Rankine power cycle. Usually the waste heat from this power system is sent to a separate radiator
array. When the MTF propulsion system is inactive, heat from the SP-100 can be sent to the Brayton cycle heat
exchanger to keep enough heat in the FLiBe so that it will remain a liquid. The pump system operates at a
lower duty cycle than when the MTF propulsion system is active. The thermal schematic for these systems is
shown in Figure 15.

**FIGURE 15. MTF Thermal Management Schematic**

**RECHARGE SYSTEM**

The recharge system is responsible for converting the compressed magnetic flux, produced by the plasma
expansion, into usable electric power for the magnetic seed field coils and the plasma guns. Because large
currents are produced in the thrust coils to accelerate the plasma, some of this current can be commutated out of
the coil and used for recharging the system. The circuit diagram for this system is shown in Figure 16.
FIGURE 16. Recharge System Schematic

The three plasma gun banks are located along different coils (numbers 8, 7 and 5 – where the coils are numbered in order of increasing size). Each individual coil is responsible for charging the bank of plasma guns which it supports. Each plasma gun has its own charging circuit connected to the thrust coil in such a way that the impedance value of the circuit lines, capacitor, and the section of the thrust coil isolated by the charging circuit terminals are equal. This ensures that only the amount of power needed to charge the capacitor can be commutated out of the thrust coil. The charging circuit requires a high duty switch for isolating the capacitor from the thrust coil. Although a spark gap system can provide the needed performance, its life is limited. An advanced switching system would ultimately be desirable.

As mentioned earlier, the seed field coils make use of a SMES, which has the capability to accept and discharge large amounts of electrical energy in a very short period of time. The SMES is connected to, and receives power from, the thrust coil conductor of the reversed conical theta pinch, which is located at the vertex of the MTF nozzle. Electrical energy, generated inductively by magnetic flux compression is absorbed into the thrust coil conductor and transmitted to the SMES. This energy is stored within the SMES in the form of a magnetic field and, at the appropriate time, is transmitted to the seed field coils to produce the initial magnetic field lines inside the MTF nozzle prior to initiation of the next fusion event. This charging circuit is shown in Figure 17.
Power is transmitted to and from the SMES, via super conducting coaxial transmission cables. Since the SMES, transmission lines, and seed field coils are all super conducting, they share a common cryogenic cooling system. Liquid nitrogen is cooled in an accumulator tank by a cryocooler and delivered to the SMES. From there it travels down the transmission lines, flows around the seed field coils, and flows back up the transmission lines to the SMES and accumulator tank for re-cooling.

Since the transmission lines must both carry and return the cryogen coolant, they require two coolant channels. Because the overall diameter of the transmission lines is not as critical as the coils, a wet mesh arrangement is not used in the interest of reducing coolant flow friction. This allows one coolant channel for each conductor in the cable. The transmission lines run along the MTP nozzle structure to the different coils in a nonsymmetrical fashion. This could affect the symmetry of the nozzle magnetic field, for which reason coaxially arranged conductors are used to reduce the magnetic field produced along the pulsed transmission lines. A radiant heat shield is also employed on the transmission lines. The resulting transmission line design is shown in Figure 18 with dimensions given in Table 2.

PROPELLANT STORAGE AND SUPPLY

Three separate propellants are required by the MTF device. Each has its own separate storage and supply system.

A 50 – 50 molar mixture of deuterium and tritium is stored as a high-pressure gas and, after suitable pressure regulation, fed to the two conical theta pinches to produce the spheromaks which ultimately merge to create the FRC target plasma. The very small quantity of plasma required to create the target (approximately 1 milligram per pulse), coupled with the need for a relatively precise mixture of the two isotopes, makes common storage attractive. Statistical mechanics naturally ensures a virtually perfect 50 – 50 mixture, without any need for complex independent metering systems for the two gases.

The plasma gun system requires two separate propellant supply systems. One feeds deuterium, for use at the very front of the gun’s discharge plasma stream. The second, which provides the bulk of the plasma, is of (normal isotope) hydrogen. For the hydrogen, which comprises the bulk of the total propellant load, volume constraints make liquid storage the only viable option. This does not pose significant problems provided some care is taken over the thermal protection system for the tanks. As the HOPE destination is in the outer solar system, maintaining low temperatures is less of a problem than in Earth orbit. High efficiency cryocoolers can be used to balance the natural heat leakage into the hydrogen and thus maintain the liquid state. Storage of the relatively small quantity of deuterium in liquid form is actually somewhat easier than normal hydrogen, the boiling point being several degrees higher. For reference, note that the entire system of plasma guns (i.e. all 48 of them) consumes approximately 50 milligrams of deuterium and 850 milligrams of hydrogen per fusion pulse.

The plasma guns can be designed to operate using gas, liquid or even solid propellants. Given their location around the MTF nozzle, in an area of elevated temperature, gaseous feed is clearly the favored option. An overall schematic for the storage and supply system is given in Figure 19.

Note that the four deuterium-tritium tanks are each shaded slightly differently. This is to denote a slight variation in the proportions of the two gases at loading. The tank intended for immediate use is loaded in a straight 50 – 50 molar mixture. The tanks intended for use later in the mission are loaded slightly tritium-rich. This is to offset the natural radioactive decay of tritium (into helium-3). The later the tank’s intended use, the more tritium-rich is its initial load.

Note also the use of gas compressors and plenum chambers. The compressors are needed to overcome line losses on the way down to the plasma guns. The plenum chambers are to ensure reasonably constant gun inlet conditions.

Provision is also made for the transfer of liquid hydrogen between the various storage tanks, in order that the vehicle center of mass can be controlled.

The masses apply to a device pulsing at a frequency of 20 Hz and with a mean jet power of 2.038 GW.

DEUTERIUM HELIUM-3 MTF

Thus far all discussion has centered upon an MTF device using a deuterium-tritium trigger to initiate fusion and an all-deuterium inner liner to provide the main fusion energy yield. There is an alternate and higher performing fusion fuel combination which should be available in the future. The trigger plasma would still consist of a 50-50 deuterium-tritium plasma, but now the plasma in the inner portion of the liner would no longer be pure deuterium; instead a 50-50 molar mixture of deuterium and helium-3 would be used. Although this combination requires a higher ignition temperature than the all-deuterium option, it is still achievable with the same deuterium-tritium trigger. Once initiated, the deuterium-helium-3 fusion reaction offers both an improved level of energy release, compared to the deuterium-deuterium baseline, and also a lower neutron flux. With both an improved energy release and a larger proportion of the liberated energy appearing in the form of charged particle kinetic energy, significant performance improvements will result. Charged particle kinetic energy can be absorbed and re-directed by the nozzle magnetic field, thus adding useful impulse to the vehicle. By comparison, neutron kinetic energy places a significant mass burden on the vehicle due to the shielding requirement. Although the deuterium-helium-3 reaction does still produce some neutrons, the number will be reduced compared with the all-deuterium inner liner option.

The drawback of this advanced fuel option is the relative scarcity of helium-3. Although it can be produced by the decay of tritium, this technique is inherently limited by the scarcity of tritium which must itself be produced by neutron bombardment within a nuclear reactor. Only trace amounts of helium-3 are available naturally on the Earth, although it is postulated that larger amounts might be available at significant depths. A plentiful supply exists in the lunar regolith, which accumulates helium-3 as a result of solar wind bombardment. Although at present this may seem a somewhat inaccessible deposit, it should be considered within the context of the cislunar infrastructure likely to be in place by the time an MTF propulsion system is in operation. By this time, with MTF providing the means for human exploration of the outer solar system, thriving transport, manufacturing and resource extraction infrastructure should be in place both at the Earth’s Lagrange points and...
on the lunar surface. The process of helium-3 extraction from lunar regolith has already been seriously studied, with encouraging results (see Wittenberg et al.).

Even more extensive sources of helium-3 are almost certainly available in the outer solar system. All of the gas giant planets appear to contain substantial quantities of the isotope. Although the delta-vs associated with atmospheric flight within a gas giant are formidable, it is possible that “mining” operations may eventually be possible. The first MTF flights to the outer solar system might use deuterium, once appropriate infrastructure has been established, subsequent flights might be able to use helium-3.
