SOLID SURFACE WETTING AND THE DEPLOYMENT OF DROPS
IN MICROGRAVITY

E. H. Trinh and J. Depew

California Institute of Technology

ABSTRACT

The complete or partial deployment of liquid samples in low gravity is primarily influenced by the interfacial properties of the specific liquid and solid materials used because the overwhelming bias of the Earth gravitational acceleration is removed. This study addresses the engineering aspects of injecting and deploying drops of prescribed volume into an acoustic positioning chamber in microgravity. The specific problems of interest are the design, testing, and implementation of injector tips to be used in a simultaneously retracting dual-injector system used in the Drop Physics Module microgravity experiment facility. Prior to release, the liquid to be deployed must be retained within a restricted area at the very end of the injectors even under dynamic stimuli due to continuous injection flow as well as to the stepped motion of the injectors, and the final released drop must have a well determined volume as well as negligible residual linear or angular momentum from the deployment process. The outcome of Earth-based short-duration low gravity experiments had been the selection of two types of injector tips which were flown as back-up parts and were successfully utilized during the USML-1 Spacelab mission. The combination of a larger contact surface, liquid pinning with a sharp edge, and selective coating of strategic tip surfaces with a non-wetting compound has allowed a significant increase in the success rate of deployment of simple and compound drops of aqueous solutions of glycerol and silicone oil. The diameter of the samples studied in the Drop Physics Module ranged between 0.3 and 2.7 cm. The tests conducted on-orbit with a manually operated small device have allowed the calibration of the volume deployed for a few drop sizes. The design for improved tips to be used during the next USML flight is based on these results.
INTRODUCTION

The shape of the free surface of liquids in contact with solids remains a subject of great interest especially when the overriding influence of gravity is removed.\(^1,2\) In addition to basic theoretical interest, the correct implementation of fluid management methods in low gravity relies on our understanding of the interfacial statics and dynamics between liquids and solid surfaces.\(^3\) Even when one is interested in the observation of the behavior of completely free three dimensional liquid surfaces, the actual process of going from a contained liquid into a containerless environment is of primary importance. The study to be described below is a limited experimental investigation designed to develop, test, and implement a specific component for the controlled deployment of liquid samples in low gravity. It was designed as a low cost flight investigation in the framework of the USML-1 Glovebox facility and in support to the on-orbit operations of the Drop Physics Module, an experiment facility dedicated to the study of the dynamics and rheology of the surface of free drops in microgravity.

I. THE PROBLEM

The objectives of the investigation of the behavior of free drops in low gravity can only be rigorously satisfied when these drops are actually deployed in a well controlled manner with well defined volume and an uncontaminated surface. The weak acoustic positioning forces used in the Drop Physics Module (DPM)\(^4\) will be effective at restraining the drop motion in a short amount of time only when the residual momentum imparted to the sample during the deployment process is negligible. The approach taken in this facility utilizes a pair of oppositely situated symmetrical injectors which simultaneously retract at high speed to leave a motionless drop in the center of the experiment chamber. This technique has been shown to be very effective when the liquid and solid deployment surface are characterized by a very large contact angle. The standard tips of the injectors are made of stainless steel and are 0.75 mm in diameter. The approach is thus to minimize contact between the drop and the injector tips by reducing their diameter to a minimum. The drop volume of interest ranged between 0.5 to 20 cm\(^3\). Figure 1a is a picture of the opposed injectors with the standard tips as they are positioned in the center of the DPM chamber without a drop, and Figure 1b shows them with a drop positioned in a desired configuration in microgravity.

Even for reasonably high contact angle (about 90° for distilled water and stainless steel) symmetrical wetting of both injector tips must be maintained in order to avoid spreading of the liquid over a single injector surface as shown in Figure 2. In this case contact was broken with the upper left injector and the liquid spread over the lower right injector surface. The subsequent remerging of the two drops produced a liquid bridge anchored at the edge of the V-shaped injector housing.
The majority of the liquids used for the drop physics experiments during the USML-1 Spacelab flight, however, displayed low contact angles with clean stainless steel surfaces. This made it quite difficult to maintain the configuration shown in figure 1b under the continuing mechanical impulses due to the liquid injection and the stepped motion of the retracting injectors. Liquids such as silicone oil and aqueous mixtures of organic surfactants will spread over the contacting solid surface upon very slight impulses. Figure 3 shows a case where a glycerol-water mixture has spread over the injector tip and past the V-shaped edge in the case of the lower right injector. The subsequent deployment was asymmetrical as evidenced by the non-simultaneous breaking of the liquid necks (Figure 3c). This asymmetry imparts linear momentum to the drop, and it results in translational oscillations of the sample in the acoustic pressure well.

The behavior of liquid bridges in low gravity has been investigated by others in the past both during parabolic flights as well as during Spacelab missions \(^5,6\), and the characteristics of liquid-solid interfaces relating to the aspects of liquid management have also been addressed in both static\(^7\) as well as dynamic cases\(^8\). In this instance we are concerned with the additional impact of the deployment dynamics on the behavior of the released drop.

II. OBJECTIVES

The objectives of this flight demonstration were simple and limited in scope: The first task was to experimentally study the dynamics of drop injection, containment, and deployment in order to design specific injector tips which would minimize all detrimental impact. The second task was to manufacture a set of tips for use in microgravity with a manually operated apparatus to be used in the Glovebox facility in order to calibrate the deployed volume. An important aspect of this investigation was the ability to also use these tips in the DPM facility, and consequently, a third objective was to utilize these tips in case difficulty was encountered during deployment in microgravity.

III. GROUND-BASED DEVELOPMENT

The process of injection, stabilization, and deployment of liquid samples can be carried out in a 15 to 20 seconds time period for liquid volumes less than 5 cm\(^3\). This has made it possible to perform experimental tests during parabolic flights of the NASA KC-135 airplane prior to the USML-1 mission. The same manually operated mechanical drop deployment device built for the Shuttle Glovebox experiment was flown aboard the KC-135 to study the dynamics of drop injection and deployment with the standard small diameter injector tips as well as with a variety of custom-designed tips. Figure 4a is a photograph of the apparatus as operated in the KC-135, and Figure 4b shows the same device on the Spacelab Workbench as it was configured for the experimental runs during the USML-1 flight.
Only distilled water and silicone oil (100 cSt viscosity) were deployed during the parabolic flight tests as they were considered the best and worst cases as far as drop deployment was concerned. All the tips tested were coated with a commercial surface treatment (trade name Nyebar).

Distilled water did not spread over the coated small diameter (0.75 and 1.5 mm OD.) cylindrically shaped stainless steel and brass tips, and could be held between the opposing injectors and deployed without difficulty. The cohesive forces of water were able to overcome the adhesive forces between the liquid and the coated solid surfaces. This allowed the controlled deployment of water drops of up to 2 cm$^3$ in volume in an environment where the background residual acceleration was on the order of 0.05 G with transients on the order to 0.1 G (G is the magnitude of the Earth-based gravitational acceleration). Figure 5 illustrates the effectiveness of the surface coating by showing the wetting of coated stainless steel tips by distilled water. Initially asymmetric wetting of the tips can be changed to symmetric wetting and positioning of the drop at the tip ends, allowing symmetric deployment of the sample.

Silicone oil, on the other hand, readily spread over the injector tip surface, and could not be deployed in a controlled manner by using small diameter cylindrical tips. Wider faced injector tips were thus designed in order to contain silicone oil and other spreading liquids. They allowed the demonstration of not only stable capture of oscillating liquid bridges, but also that of successful deployment of silicone oil drops as shown in Figure 6. Low gravity tests aboard the KC-135 have therefore established that the fast retraction of opposed injectors allowed the deployment of silicone oil drops of up to 2 cm$^3$ in volume with negligible residual momentum even with tips having a significant contact surface area (18 mm$^2$). This led to the selection of two tip designs for implementation in microgravity: type a tips have a flared out face of 9.5 mm in outer diameter and 1.75 mm in inner diameter and type b tips are cylindrical in shape with an outer diameter of 4.75 mm with a inner diameter of 1.55 mm. These two different designs are shown in Figures 7 where they have been mounted on the Drop Physics Modules injectors. Both these types of tips have 90 degrees sharply machined edges, and the flight units have been completely surface treated with a Nyebar solution through a dipping and bakeout procedure.

IV. EXPERIMENTS DURING THE USML-1 FLIGHT

Drop deployment experiments using the designed tips described above have been carried out both in the Drop Physics Module facility as well as on the Spacelab Workbench. Contrarily to initial plans, the tips were successfully used in the Drop Physics Module prior to tests in the Glovebox facility. Since feasibility had been demonstrated, the goals of the Glovebox demonstration were restricted to manual deployment and calibration of large drop volumes from 5 to 12 cm$^3$. 

586
A. Spacelab Workbench tests

Initially scheduled at the beginning of the mission for performance in the Glovebox facility, the drop deployment tests were postponed until the seventh day, and were carried out on the Spacelab workbench. The experimental set-up is shown in figure 4b, and the Orbiter video camcorder was used to record the experiments. The apparatus was gray-taped to the workbench surface, and existing Spacelab and workbench lighting were utilized.

Working well below the stability limit for liquid bridge (cylindrical zones with aspect ratio only up to 2.6 were generated), very symmetric manual injection and deployment of water, aqueous mixtures of glycerin, and surfactant solutions was carried out and video recorded or transmitted live to the ground. Figure 8 shows the sequence of injection and deployment of a 5 cm$^3$ water drop.

Detailed observation of the dynamics of drop deployment reveals that for larger droplet volumes (greater than 5 cm$^3$) the majority of the liquid remains undisturbed and motionless as the injector withdraw symmetrically at high speed. The necks on both sides of the central drops elongate and break leaving no or several satellite droplets depending on the liquid viscosity. The small fraction of the liquid remaining on the injector faces (5 to 10%) appears to primarily depend on the size of the contacting surfaces and on the retraction velocity.

The results of the measurement of the deployed drop volumes are displayed in table I. These data have been gathered for distilled water and for the wide-faced tips. Three different desired volumes were investigated, and three different runs were carried out for each volume. The drops could not be captured in mid-air as planned, but they were retrieved from the walls of the Lucite chamber on which the liquid did not spread, thus allowing recovery of the entire sample. The volume measurements were obtained through a calibrated micrometer-driven syringe with an accuracy of 0.005 cm$^3$. The reproducibility obtained through this limited set of measurements indicate a volume reproducibility of +/-2 % at worst. Part of this variation might be attributable to the variation in retraction velocity inherent of the manually operated device. The stepper motor-controlled injection system of the Drop Physics Module provides more reproducibility in the retraction velocity as well as higher rates.

B. Drop Deployments in the Drop Physics Module

Both types of tips were successfully used during the experiment runs of the DPM facility for the deployment of simple as well as compound drops (a drop within a drop) of aqueous mixtures of glycerol, silicone oil, and hydrocarbon compounds. The sharp 90° edges of the tips contained the liquid within the required surfaces during the first injection and deployment, but the sudden stop at the end of the injector retraction invariably drove the liquid beyond the pinning edge, and allowed the spreading of the liquid.
over the body of the tips. The liquid containment for silicone oil was so precarious that in one particular instance the bursting of a bubble caused the liquid to spread beyond the pinning edge.

Figure 9 displays a series of video frame printouts from a recorded deployment of a drop of water-glycerol mixture of 50 cSt viscosity using the cylindrically shaped tips (type b). Near perfect symmetry can be observed by noting the breaking points of the necks on each side of the drop as well as the symmetrical shapes of the residual shape oscillations. Figure 10 is a similar series of video frames depicting the deployment of a 100 cSt silicone oil drop using the wide-faced injector tips (type a). Good symmetry can be observed once again. The deployed sample remained motionless in both instances.

Type b tips were also successfully used to inject and to deploy compound drops of a water-glycerol solution into a silicone oil drop.

**CONCLUDING REMARKS**

Liquid wetting and spreading acquire greater importance in microgravity when one becomes concerned with containment and material contamination management. Notoriously difficult to handle liquids such as silicone oil and surfactant solutions must be restricted to limited areas by physical barriers such as a sharp pinning edge. Although this latter technique is not foolproof, it appears to be effective in normal acceleration conditions of the Space Shuttle. In the restricted area of drop deployment, the results of these low gravity tests show that a compromise involving a larger liquid-solid contacting area will still allow the reproducible deployment of drops with controlled volumes. Because orbital operation time is extremely valuable, drop deployment procedures which minimize liquid clean-up and sample translational oscillation damping times must be adopted.

Improvements based on these results will involve the elimination of sudden acceleration pulses in the direction tending to induce liquid spreading, sharper pinning edges (30 or 45° instead of 90°), slower liquid injection rates or larger injector bores, and finally real-time crew interaction with the injection/deployment mechanism.

Figure 1  1a. Small diameter standard DPM injector tips and housing as viewed along the Z axis of the experiment chamber.

1b. Nominal configuration for a drop to be deployed. The small contact surface between the tips and the drop and the symmetrical retraction of the injectors insure that a very small fraction of the liquid remains on the injector tips and that minimal momentum is imparted to the released sample.
Figure 2 Still video frame sequence showing the loss of contact with one injector tip and the subsequent spreading of the liquid (distilled water) all the way to the injector housing collar (V-shaped solid surface). For a non-spreading liquid like water, this can be prevented by maintaining a larger contact surface with both tips.
Figure 3 In these video frames a water-glycerol mixture has spread past the V-shaped housing to the O-ring on one side of the lower-right injector (a). Subsequent deployment creates an initial time lag in the breaking of the liquid neck connecting the drop to the more wetted injector (b and c). This unbalance does not necessarily result in the induction of linear momentum, but it influences the initial dynamics of the released sample.

Discussion

Question: Your syringes are much larger than those used in PCG (Glovebox) experiment. You also have a lot of different types of fluids. What can you comment about the bubbles?

Answer: I don't want to talk about it. We had a lot of problems with bubble deployment. They were of different sources than yours. I think most of our bubble deployment problems came from the tubing that we are using. I am not really convinced of that. I think it is the way we connected the syringes to the deployment tips that was the weak point. There were places where we could generate bubbles, not by negative pressure, but by just flowing by entraining air. With bubbles, it is a major problem.

Question: Did you suffer the mental retardation effect as Larry DeLucas?

Answer: I could not tell the difference. No. That is not true. Larry is very right. Things slow down tremendously. I had to take a lot more time to do things, things that seem to be really easy, and think about things a lot longer. That is the major part of things going real slow. Factors for this probably include the pressure that you have 200 people watching you, and great PIs talking to you. There is a great bit of pressure, and various sources contributing to that are many. I think that having a lot of fluids in your head does not help either. But I agree with Carl, I think after a few days I began to get in the groove, and I came up to 100%, or whatever level I am supposed to be at.
