Received ;

Abstract.
A detailed analysis of the radiative and Auger de-excitation channels of K-shell vacancy states in Fe ii–Fe ix has been carried out. Level energies, wavelengths, A-values, Auger rates and fluorescence yields have been calculated for the lowest fine-structure levels populated by photoionization of the ground state of the parent ion. Different branching ratios, namely Kα2/Kα1, Kβ/Kα, KLM/KLL, KMM/KLL, and the total K-shell fluorescence yields, ωK, obtained in the present work have been compared with other theoretical data and solid-state measurements, finding good general agreement with the latter. The Kα2/Kα1 ratio is found to be sensitive to the excitation mechanism. From these comparisons it has been possible to estimate an accuracy of ~10% for the present transition probabilities.

Key words. atomic data – atomic processes – X-rays: spectroscopy

1. Introduction

The iron K lines appear in a relatively unconfused spectral region and have a high diagnostic potential. The study of these lines has been encouraged by the quality spectra emerging from Chandra and by the higher resolution expected from Astro-E and Constellation-X. In addition there is a shortage of accurate and complete level-to-level atomic data sets for the K-vacancy states of the Fe isonuclear sequence, in particular for the lowly ionized species. This undermines line identification and realistic spectral modeling. We are currentlyremedying this situation by systematic calculations using suites of codes developed in the field of computational atomic physics. Publicly available packages have been chosen rather than in-house developments. In this context, complete data sets for the n = 2 K-vacancy states of the first row, namely Fe xvii–Fe xxv, have been reported earlier by Bautista et al. (2003) and Palmeri et al. (2003), to be referred to hereafter as Paper I and Paper II, and for the second row (Fe x–Fe xvii) by Mendoza et al. (2003), to be referred to as Paper III.

The K lines from Fe species with electron occupancies N > 17 have been studied very little. Jacobs & Rozsnyai (1986) have computed fluorescence probabilities in a frozen-core approximation for vacancies among the nℓ subshells of the Fe isonuclear sequence. Kaastra & Mewe (1993) have calculated the inner-shell decay processes for all the ions from Be to Zn by scaling published Auger and radiative rates in neutrals. Both of these studies ignore multiplets and fine-structure. Otherwise, the bulk of the data in the literature is devoted to solid-state iron. Regarding wavelengths and line intensity ratios, numerous references are listed in Höfler et al. (1997) who measure the Kα1,2 and Kβ1,3 emission lines of the 3d transition metals using a high-precision single-crystal spectrometer. Fewer publications are available on the experimental K Auger spectra: Kovalik et al. (1987) have derived the KLM/KLL and KMM/KLL ratios from the Auger electron spectrum of iron produced by 57Co decay, and Némethy et al. (1996) have measured the KLL and KLM spectra of the 3d transition metals but have not determined the KLM/KLL ratio. Concerning K-shell fluorescence yields, measurements covering the period 1978–93 have been reviewed by Hubbell et al. (1994) following major compilations by Bambukat et al. (1972) and Krause (1979).

The present work is a detailed analysis of the radiative and Auger de-excitation channels of the K-shell vacancy states in the third-row species Fe ii–Fe ix. Energy levels, wavelengths, A-values, Auger rates and fluorescence yields have been computed for the lowest fine-structure levels in configurations obtained by removing a 1s electron from the ground configuration of the parent ion. In Section 2 the numerical method is briefly described. Section 3 outlines the decay trees and selection rules. Results and discussions are given in Section 4, followed by a summary and conclusions (Section 5). All the

June 16, 2003
We have focused our calculations on the Fe K-vacancy states radial integrals and for which the complete expression is given in Eq. (11) of Palmeri et al. (2001). The calculated Auger rates in a single-configuration approach.

3. Photoionization selection rules and decay trees

We have focused our calculations on the Fe K-vacancy states populated by photoionization of the ground state of the parent

\[ \mu \Rightarrow (25^+1) L_J + \gamma \rightarrow [1s] \mu \Rightarrow (25^+1) L'_J + e^- \]  

where \( \mu \) is the outer configuration of the ground state, i.e. \( 3d^64s^2 \) in \( Fe \) i, \( 3d^64s \) in \( Fe \) ii and \( 3d^5N \) \((N = 1 - 6)\) in \( Fe \) m-Fe xii, [1s] denoting a K hole. In Eq. (2), K-shell photoionization leads to a p wave with selection rules specified by Rau (1976): \( L' = L, S' - S = \pm 1/2 \) and \( J' - J = \pm 1/2, \pm 3/2 \). Therefore, only few states are expected to be populated.

The radiative and Auger decay manifolds of a K-vacancy configuration [1s]\( \mu \) can be outlined as follows:

- Radiative channels

\[ [1s] \mu \Rightarrow [3p] \mu + \gamma \beta \]  
\[ Ke \Rightarrow [2p] \mu + \gamma \alpha \]  

- Auger channels

\[ [1s] \mu \Rightarrow [3s]\mu^2 + e^- \]  
\[ [3p]\mu^{-1} + e^- \]  
\[ [3s]\mu^{-1} + e^- \]  

where the negative exponent of \( \mu \) stands for the number of electrons that have been extracted from the outer subshells. In the radiative channels, forbidden and two-electron transitions have been excluded as it has been confirmed by calculation that they display very small transition probabilities (log \( A_\gamma < 11 \)). Therefore, the two main photo-decay pathways are the result of the 2p \( \rightarrow \) 1s and 3p \( \rightarrow \) 1s single electron jumps that give rise respectively to the \( K\alpha \) (\( \sim 1.94 \)) and \( K\beta \) (\( \sim 1.75 \)) arrays.

It has also been numerically verified that the participator Auger channels (KMM(p) and KLM(p)) contribute less than one percent to the total Auger widths, and hence, they have not been taken into account. Of primary interest in the present work is the branching ratios of the \( K\alpha \), \( K\beta \), KMM, KLM and KLL channels and their variations with electrons occupancy \( N \).

4. Results and discussion

Centroid wavelengths for the \( K\alpha \) and \( K\beta \) unresolved transition arrays (UTAs) computed with \( HFR \) are presented in Table 1, including also a comparison with experiment. For the \( K\alpha_1 \) and \( K\alpha_2 \) lines, it can be seen that the agreement with the solid-state measurements by Hölzer et al. (1997) (\( \sim 0.5 \) mA) is somewhat better than that with the EBIT results for Fe x (Decaux et al. 1995) of within 2 mA, and the slight blueshift with increasing \( N \) predicted by \( HFR \) is consistent with experiment. A small

Table 1. Comparison of centroid wavelengths (Å) for the $\text{K}\alpha$ and $\text{K}\beta$ unresolved transition arrays in Fe ions with $17 \leq N \leq 25$. The $\text{HFR}$ wavelengths have been weighted with the fluorescence yields. Experimental wavelengths for Fe x ($N = 17$) are from Decaux et al. (1995) and for solid-state iron from Höfler et al. (1997).

redshift with $N$ is also found for the $\text{K}\beta$ array. On the other hand, as shown in Figure 1, the present findings contrast with the steeper redshift for both UTAs obtained from the data by Kaastra & Mewe (1993).

In Table 2, $\text{K}\alpha_2/\text{K}\alpha_1$ intensity ratios are tabulated for different ionization stages. Two cases have been considered: HFR1, only the decay lines from the K-vacancy levels populated by the photoionization of the respective ground state are included; and HFR2, all the transitions from the levels belonging to the [1s](3d + 4s)$^{M+1}$ complex are taken into account. Noticeable
just under 20%. The computed results by corrections to explain the discrepancy of their data with other (1997) mention a possible systematic deviation in one of their measurements. On the other hand, the Dirac-Fock ratios by plotted along with the value recommended by Hubbell et al. Slivinsky the dict's a decrease of the ratio with in Perujo et al. (1987) does not take into account the blend with which theory does not include (Verma 2000). The value quoted and Jacobs is comparable with that among the solid-state experiments of Perujo et al. (1987; Rao et al. 1986; Berényi et al. 1978; Salem et al. 1972; Slivinsky & Ebert 1972; Hansen et al. 1970) have been scaled down by 8.8% in order to extract the radiative-Auger (5%) and Kβ3 (3.8%) satellite contributions from the Kβ UTA which theory does not include (Verma 2000). The value quoted in Perujo et al. (1987) does not take into account the blend with the Kβ3 satellite and has been corrected accordingly. With the exception of the values by Kaastra & Mewe (1993), theory predicts a decrease of the ratio with N, and the theoretical scatter is comparable with that among the solid-state experiments of just under 20%. The computed results by HFR, AUTOSTRUCTURE and Jacobs & Rozsnyai (1986) for N = 25 are in good agreement with the bulk of the experimental values (Perujo et al. 1987; Rao et al. 1986; Berényi et al. 1978; Salem et al. 1972; Slivinsky & Ebert 1972; Hansen et al. 1970). Hölzer et al. (1997) mention a possible systematic deviation in one of their corrections to explain the discrepancy of their data with other measurements. On the other hand, the Dirac–Fock ratios by Scofield (1974) and Jankowski & Polasik (1989) at N = 25 appear significantly higher. We have therefore proceeded to verify these values by using the same code (MCDF-SAL) as in Jankowski & Polasik (1989), and as shown in Figure 2, they are accurately reproduced; moreover, a similar decrease in the ratio with N is also obtained with this method. The spread of the different data sets in this comparison indicates a probable accuracy of our HFR transition probabilities of ~ 10%.

A decrease with N is also predicted by HFR for the Auger KLM/KLL and KMM/KLL ratios (see Figure 3). For Fe II, present results are in excellent accord with the measurements of Kovalik et al. (1987) and other theory (Chen et al. 1979; Bhalla & Ramsdale 1970) but somewhat higher than the older experimental estimate of Mehlhorn & Albridge (1963). The total K-shell fluorescence yields, ωK, for Fe ions with 10 ≤ N ≤ 25 are presented in Figure 4. In both HFR and AUTOSTRUCTURE data sets, the fluorescence yields have been computed for fine-structure K-vacancy levels:

\[
\omega_K(i) = \frac{A_i}{A_i + A_d(i)}. \tag{10}
\]

In order to display the effect of the level population, we report in Figure 4 the value for the first K-vacancy level and the yield averaged over all the K-vacancy levels. As expected, the fluorescence yield is independent of the population mechanism in the third row ions where the Kβ, KLM and KMM decay channels become spectators. Given the complexity of level-to-level calculations of Auger rates, it has not been possible to compute fluorescence yields with AUTOSTRUCTURE for N > 17. The most recent experimental measurements in the solid (Solé 1992; Pious et al. 1992; Singh et al. 1990; Bhan et al. 1981) are plotted along with the value recommended by Hubbell et al.
Palmeri et al.: K lines in Fe II–IX

Fig. 5. Simulations carried out near 6.4 keV with the XSTAR modeling code for several values of the ionization parameter $\xi$.

They show a scatter within 10% and are slightly lower than our HFR value for $N = 5$, i.e. 5 to 10% with respect to Hubbell et al. (1994) and Bhan et al. (1981) respectively. This is not a significant discord considering the expected accuracy of our fluorescence yields (∼ 20%) as discussed in Paper III. As mentioned in the previous section, the missing participator Auger channels will not contribute significantly to the Auger widths (less than 1%). Concerning the shake-up channels, they will not affect the Auger widths because they are due to mixing between valence shell configurations which have the same Auger widths. We have verified that this is the case in a simple calculation ([1s][3d + 4s]$^8 \rightarrow [2p]^2[3d + 4s]^8 + ks$). Data by Kaastra & Mewe (1993) have been corrected so as to reproduce the best solid-state yields compiled in Bambynek et al. (1972) and are therefore somewhat lower than our values. Results by Jacobs & Rozsnyay (1986) for $N > 12$ predict a substantially lower yield.

In order to evaluate the impact of the new atomic data on Fe K-line modeling, the data sets generated in the present work and those in Papers I–III have been included in the XSTAR modeling code (Kallman & Bautista 2001). Runs for different ionization parameters, $\xi$, are shown in Figure 5. The other parameters have been assigned the following values: cosmic abundances; a gas column density of $10^{16}$ cm$^{-2}$; a gas density of $10^{12}$ cm$^{-3}$; an X-ray source luminosity of $10^{38}$ erg/s; a power-law index of 1; and energy bins (or channel widths) of 1 eV. In Figure 5, one clearly sees that the UTA centroid is redshifted when $\xi$ goes from 0.001 to 1 and then blueshifted for $\xi > 1$. The shape of the UTA changes also considerably for $\xi > 1$ where the ionization balance favors the first and second row ions.

Electronic Tables 3–4 list radiative and Auger widths for 295 energy levels; and wavelengths, A-values and fluorescence yields for 396 transitions.

5. Summary and conclusions

Following the findings of our previous study on the second-row iron ions (Paper III), the HFR package (Cowan 1981) has been selected to compute level energies, wavelengths, decay rates and fluorescence yields for the K-vacancy states in Fe II–Fe IX. The calculations have focused states populated by ground-state photoionization. Due to the complexity of the level-to-level Auger calculations, we have employed a compact formula
Palmeri et al. 2001) to compute Auger widths from the HFR radial integrals.

The HFR centroid wavelengths for the Ka and KB UTAs in Fe II reproduce the solid-state measurements (Hölzer et al. 1997) to better than 1 mA. Moreover, the red shift predicted by HFR for the Ka lines in species with higher ionization stage is in accord with the EBIT wavelengths in Fe x (Decaux et al. 1995) thus contradicting the previous trend specified by Kastra & Mewe (1993). We have also carried out extensive comparisons of different HFR branching ratios, namely Ka2/Ka1, KB/Ka, KLM/KLL, KMM/KLL and WK, with other theoretical and experimental data. The present ratios for Fe II are in good agreement with the solid-state measurements, and the KadKaI ratio has been found to be sensitive to the excitation mechanism. It has been possible from these comparisons to estimate an accuracy of ~10% for the HFR transition probabilities.

The new atomic data sets for the whole Fe isonuclear sequence that have emerged from the present project are providing a more reliable platform for the modeling of Fe K lines. Preliminary simulations of the emissivity of a photoionized gas with XSTAR (Kallman & Bautista 2001) have shown Ka line profiles and wavelength shifts that are sensitive to the ionization level of the gas. Further work will therefore be concerned with improving diagnostic capabilities by means of accurate K-shell photoionization and electron impact excitation cross sections.
