**UAV Flight Control using Distributed Actuation and Sensing**

An array of effectors and sensors has been designed, tested and implemented on a Blended Wing Body UAV. This UAV is modified to serve as a flying, controls research, testbed. The effector/sensor array provides for the dynamic vehicle testing of different controllers and also for the study of decentralized control techniques. Each wing of the UAV is equipped with twelve distributed effectors that comprise a segmented array of independently actuated, control surfaces. A pressure sensor is installed at the base of each effector in order to provide measure of the deflection of effector. The fully instrumented wings are tested in a wind tunnel. The measured pressures are used to develop a simple, but accurate prediction method for the deflection of the effectors. Numerical analysis using the CMARC panel code verifies the utility of this prediction method.

**Abstract**
An array of effectors and sensors has been designed, tested and implemented on a Blended Wing Body UAV. This UAV is modified to serve as a flying, controls research, testbed. The effector/sensor array provides for the dynamic vehicle testing of different controllers and also for the study of decentralized control techniques. Each wing of the UAV is equipped with twelve distributed effectors that comprise a segmented array of independently actuated, control surfaces. A pressure sensor is installed at the base of each effector in order to provide measure of the deflection of effector. The fully instrumented wings are tested in a wind tunnel. The measured pressures are used to develop a simple, but accurate prediction method for the deflection of the effectors. Numerical analysis using the CMARC panel code verifies the utility of this prediction method.
ABSTRACT

An array of effectors and sensors has been designed, tested and implemented on a Blended Wing Body Uninhabited Aerial Vehicle (UAV). This UAV is modified to serve as a flying, controls research, testbed. This effector/sensor array provides for the dynamic vehicle testing of controller designs and the study of decentralized control techniques. Each wing of the UAV is equipped with 12 distributed effectors that comprise a segmented array of independently actuated, contoured control surfaces. A single pressure sensor is installed near the base of each effector to provide a measure of deflections of the effectors.

The UAV wings were tested in the North Carolina State University Subsonic Wind Tunnel and the pressure distribution that result from the deflections of the effectors are characterized. The results of the experiments are used to develop a simple, but accurate, prediction method, such that for any arrangement of the effector array the corresponding pressure distribution can be determined. Numerical analysis using the panel code CMARC verifies this prediction method.
ACKNOWLEDGMENTS

The work reported here was supported by the NASA Langley Research Center under the grant NAG1-01069. The technical monitor was David L. Raney of the Dynamics and Control Branch. The authors gratefully acknowledge this support and the technical monitor's interest and strong encouragement.

1. INTRODUCTION

1.1 Aircraft Morphing Concepts
The National Aeronautics and Space Administration (NASA) Aircraft Morphing program has the objective of integrating research from a broad range of disciplines in order to incorporate smart technologies into high payoff aircraft applications. Smart technologies may be defined as embedded actuation, sensing, and control logic that are tightly coupled in a feedback loop. Therefore, the primary focus for the Morphing program is to develop closed-loop devices having dynamic actuation, local sensing, and feedback control. Consequently, a combined approach to control systems and system identification is being used in the Morphing program to address the control laws and controller responses required for the individual devices, as well as addressing the global requirements for distributed arrays of devices that are used to achieve an overall system benefit. Thus, it is within this framework that NC State and NASA have partnered to develop a flying controls test bed that is equipped with distributed actuation and sensing.

1.2 UAV Overview and Research
Uninhabited Aerial Vehicles (UAVs) are used for a wide range of purposes including military, civilian and research. In military applications, the UAV can be used for in-field reconnaissance or high altitude surveillance. The U.S. military is also developing Uninhabited Combat Aerial Vehicles (UCAVs) to complement and/or replace fighter aircraft. Civil use of UAVs include aerial photography and observation of traffic patterns. In agriculture UAVs can be used to inspect crops and provide local applications of pesticide and/or herbicides. High altitude, long range UAVs also serve as upper atmospheric weather stations. Finally the use of highly instrumented UAV’s in research applications provides a
quick, safe and inexpensive method to validate a wide variety of novel designs and concepts.\textsuperscript{11,12}

New flow control methods are under investigation to reduce fuel consumption, increase range/endurance, increase control authority and enhance maneuverability throughout the entire flight envelope of an air vehicle.\textsuperscript{13} This approach is in contrast to traditional, passive control approaches that have inherently poor performance at off-design conditions. In general, active flow control devices can yield more reduced drag, increased lift and better control of unsteady aerodynamics than passive devices.\textsuperscript{14}

Recent activity at NC State's Flight Research Laboratory has demonstrated the advantages of highly instrumented UAVs in validating flow and flight control technologies under actual flight conditions.\textsuperscript{15,16} In the current work an existing UAV platform is modified to evaluate multiple controller designs. An innovative replacement for traditional flaps (ailerons, elevators, rudders, etc.) is used in order to gain enhanced control of the aircraft.

\section*{1.3 Decentralized Control Techniques for Distributed Systems}

New developments in decentralized control techniques have provided methods to control distributed arrays with a large number of individual elements. These techniques have been useful in a wide variety of applications. Studies have shown that the decentralized control methods provide a viable option for distributing air/ground traffic separation.\textsuperscript{17} Several studies have investigated the robust control of multiple vehicles, including UAVs, traveling in formation and show that a decentralized control method provides optimal control while reducing the complexity of the control algorithm.\textsuperscript{11,18} Furthermore, recent discoveries in material science and fluidics have been used to create a variety of shape-change and fluidic effector devices to enable new approaches to aerospace vehicle flight
control. Microelectromechanical systems (MEMS) make feasible the concept of combining actuation, sensing, computing, and telecommunications to produce a very large array of distributed configurations with unprecedented capabilities for control. Future aerospace vehicles might use distributed arrays with hundreds of such devices for stabilization and maneuver control, thereby augmenting or replacing conventional ailerons, flaps and/or rudders.

The underlying theme in each of the distributed systems is that standard control techniques have severe limitations because the overall system is rich and complex, and requires high levels of connectivity and massive computations. However, many systems contain similar elements that interact with their nearest neighbor in a simple and predictable fashion. The goal of developing decentralized control techniques is to obtain tractable algorithms for controlling the simple systems and then applying the technique to a more vast, overall scheme.

The current work develops a test-bed with a distributed actuation and sensing suite that provides the capability to test and evaluate a large number of controllers and control methods, such as decentralized control. Control objectives include active separation control, stabilization and maneuver control, disturbance rejection or upset recovery, mission-adaptive performance enhancement, and failure accommodation. In addition to the aforementioned control objectives, reduced fuel consumption, enhanced maneuverability and reconfigurability are potential benefits of distributed effector and sensor arrays. Sophisticated controller designs using elegant inputs, such as modal shapes that only vary amplitude and frequency across the effector array will be used to provide multi-axis aircraft control.
1.4 NASA Morphing Wing

The Smart Wing program was developed and sponsored by DARPA, AFRL and NASA. The program evaluated smart materials through a multi-disciplinary investigation for high payoff aircraft. Phase 1 of the Smart Wing program concluded with wind tunnel testing in 1997. One aspect of the Smart Wing design was a Shape Memory Alloy (SMA) actuated trailing edge device that replaced a traditional control surface. This design produced a contoured wing, or a hingeless control surface (Figure 1). The benefits of a contoured wing are illustrated in Figure 2. The conventional hinged flap, due to its abrupt change in curvature, is more prone to separation than the smooth transition of the contoured control surface. Figure 2 shows that the contoured wing yields a higher value of the maximum lift coefficient, $C_{l_{\text{max}}}$, thus increasing the stall envelope of the aircraft. Another benefit is an increase in the upper corner of the drag bucket, which indicates an increase in $L/D_{\text{max}}$.

Wind tunnel testing of the Smart Wing was conducted at NASA Langley’s 16 ft Transonic Dynamic Tunnel on a 16% scale F/A - 18 E/F model. The model was tested with both the traditional, hinged control surfaces and the contoured, SMA actuated surface. The Smart Wing showed significant aerodynamic improvements. Figure 3 shows that for any given angle of attack, $\alpha$, there is an increase in the lift coefficient, $C_{l}$, resulting in 8% increase in lift. The pressure distribution around the airfoil, Figure 4, shows that the Smart Wing produces increased amount of suction on the upper surface near the trailing edge of the airfoil. This increase in negative pressure directly contributes to the increased lift. The Smart Wing also shows improved aerodynamic performance by using the contoured wing design.
1.5 Objectives of Project

The current project develops a UAV test-bed to test decentralized control methods using a distributed array of contoured control surfaces. The effector and sensor suite are designed to evaluate, in the future, a wide range of control objectives. The implementation of the distributed effector array is illustrated in Figure 5. The continuous control surface proved very difficult to manufacture; therefore, in the current work the effector array is approximated with a series of segmented and independently actuated effectors. Surface pressure measurements will be used as sensors for the array. A recent study has shown that as few as four pressure measurements on an airfoil can provide information on the overall lift. Thus the pressure sensors are designed to provide feedback in the controllers. Each effector is paired with a single sensor; therefore, the effector/sensor pair forms a subsystem. Each subsystem is first characterized and then the subsystems are used to predict the response for the more complete effector/sensor array.
2. EXPERIMENTAL AND NUMERICAL APPROACH

2.1 Experimental Set-Up

2.1.1 Wind Tunnel

The NC State Subsonic Wind Tunnel is a closed return wind tunnel with a test section 32” high * 45” wide * 46” long. The wind tunnel operates at a maximum dynamic pressure of 12 lb/ft²; thus the maximum velocity is approximately 85 ft/s. The tunnel is equipped with Plexiglass® side walls at the test section. A solid door was constructed to replace one of the Plexiglass® side walls. This door is equipped with a 6” offset splitter plate onto which the model is mounted. The splitter plate is used to eliminate the influence of the wind tunnel walls’ boundary layer on the model and to position the model in the center portion of the test section.

2.1.2 Instrumentation

2.1.2.1 Pressure Measurement System

Two pressure scanning devices are used to measure the surface static pressures on the model. A Scanivalve® system equipped with 96 channels and a ±3.5” H₂O transducer is used as the primary pressure measurement system. A Pressure Systems, Inc. Electronic Scanning Pressure (ESP) module was also used. The ESP module has 16 independent ±10” H₂O transducers that are contained within a lightweight and compact case; this module is capable of measuring up to 32 channels.

2.1.2.2 Servo Serial Boards

Servo serial boards, manufactured by BASIC-X™ are used to command the positions of the servos/effectors. The boards allow the command of 256
positions for each servo. Up to eight serial servo boards can be linked together therefore providing independent control of up to 64 servos using a single serial connection.

2.1.3 UAV BWB Delta
The testbed is the UAV BWB (Blended Wing Body) DELTA that was designed, built and flight tested at NC State (Figure 6). The flying wing platform is similar to the design of the NASA BWB. The root chord and tip chord are 58" and 5 1/4", respectively. The 9.5' wingspan aircraft is powered by an Aviation Microjet Technology™ (AMT) mini-turbojet engine that is rated at 18-lbf static thrust. The cruise and stall speeds are 120 ft/s and 45 ft/s, respectively. The UAV has no landing gear; instead the aircraft is dolly-launched and skid recovered. The aircraft has a dry weight of 30 lb. with a payload capacity of 15 lbs. BWB DELTA is an ideal candidate for the effector array because the flying wing design allows the trailing edge surfaces of the aircraft to provide pitch and/or roll control. The UAV BWB DELTA has removable outboard wing panels; therefore, new wing panels equipped with the distributed effectors were constructed.

2.1.4 Wing Panels
The outboard wing panels of the aircraft have a 21" root chord with a 5 1/4" tip. The airfoil section is a NACA 0015. The wing span is 31 1/4". Figure 7 shows details of the wing during construction. The skins for the wings are made of a wet-laminate fiberglass/graphite composite which incorporates a 1/8" Korex™ honeycomb core. The internal formers are 1/8" birch plywood. Aluminum bars are integrated into the skin to provide attachment points for the effectors. A hatch provides access to all of the servo motors, effectors, and pressure ports.
Twelve effectors, adjacent to each other, are installed on each wing. The effector #1 is at the root and effector #12 is 18” from the root. Because of the thin cross-section at the most outboard portion of the wing, a conventional hinged control surface is installed. A second conventional control surface is located on the main body section of the aircraft. Thus the arrays of distributed effectors are backed-up by conventional surfaces which give redundancy to the control surfaces of the aircraft. Figure 8 shows the starboard wing with the complete distributed effector array.

Each outboard wing panel equipped with the distributed effectors, servos and other hardware has a weight of 3.5 lbs. The baseline wing panels have a weight of 2.25 lbs. Thus, the net increase in the weight of the wings is 1.5 lbs. There are additional power requirements to operate the 24 servos (one for each effector); however, the additional batteries are used to replace the ballast that is required in the nose of the aircraft. Thus the overall weight increase of the modified wing panels and its accessories is less than the available payload weight of 5 lbs.

2.1.5 Distributed Effectors and Sensors

2.1.5.1 Effectors

The arrays of independently actuated surfaces, also termed effectors, are designed to operate with the same bandwidth (1-2 Hz) and maximum deflection (±15°) as the conventional control surfaces. Therefore the modified vehicle can operate similar to the baseline vehicle when the effectors are deployed as a conventional surface.

The actuation of the effectors is provided by commercially available, off-the-shelf servo motors, Hobbico™ CS-5 nano-servos. The design of the effectors incorporates a hingeless, contoured control surface. Each effector is comprised of two rectangular elements of thin spring steel having dimensions of 0.007”
(thickness), 1.5” (width) and 4” (length), one each on the upper and lower surfaces. The effectors are deflected by the servos through a pull-pull wire linkage; the opposing surface restores the actuated surface to its neutral position. An undeflected and deflected full-scale prototype of an effector is shown in Figure 9.

2.1.5.2 Sensors

An array of 24 surface pressure taps (12 taps per wing) is used to monitor the deflections of the effectors. One pressure tap, 0.040” in diameter, is located 4.05” from the trailing edge of each effector. The pressure taps are equally spaced at intervals of 1.5” in the spanwise direction with the first pressure tap located 0.75” from the root chord. Therefore there is one pressure tap located immediately forward of each effector. The pressure tubulations are connected to the pressure scanning system through 0.040” diameter nylon tubing.

2.2 Computational Methods

2.2.1 XFOIL

The effect of Reynolds number, flap hinge location, and flap deflection are examined using XFOIL. XFOIL is a two-dimensional inviscid analysis code based on the linear vorticity stream function. In the present work an airfoil, whose undeflected cross-section is the NACA 0015, is examined. The CAD program, Unigraphics™, is used to generate undeflected and deflected trailing edge airfoil sections. The contour of the modified wing panel is modeled by the deflected trailing edges of the airfoil section. A range of deflected airfoil sections with hinge locations of x/c = 0.4-0.9 and flap deflection angles of 10-60° are examined.
2.2.2 CMARC
The aerodynamic analysis code CMARC is used to examine the pressure distribution on the UAV BWB DELTA equipped with the array of distributed effectors. CMARC is a three-dimensional, inviscid, panel code method based on potential flow theory. The geometry of the UAV, with and without deflection of the effectors, is modeled in Unigraphics™. A representative aerodynamic model of the wing panels is shown in Figure 10; the inset shows a close-up of the deflected effectors.
3. RESULTS AND DISCUSSION

Numerical and experimental results of the performance of the distributed effector and sensor are presented in this chapter. The performance is first examined using the two-dimensional analysis code XFOIL (3.1); then a three-dimensional analysis using CMARC (3.2) is presented; finally the results of an experimental wind tunnel investigation are presented (3.3).

3.1 XFOIL Results

The outboard wing panel of UAV BWB DELTA is tapered. This variation in the geometry results in different cross-sections across the span of the effector array. XFOIL provides a quick method to isolate the effect of the varying geometry by examining two-dimensional, airfoil, cross-sections of the wing. This analysis delineated the influence of changing flap deflection, Reynolds Number and hinge location. Also the potential aerodynamic benefits of a contoured design versus a conventional hinged flap are examined.

3.1.1 Effect of Flap Deflection

Figure 11 shows the effect of changing flap deflection, $\delta_r$. Three airfoils with deflections of $10^\circ$, $15^\circ$ and $20^\circ$ deflections are presented. The hinge location is $x/c = 0.7$ and the Reynolds number is $1\times10^6$. The lift and pitching moment coefficients are plotted versus angle of attack, $\alpha$. As the deflection angle is increased, the $C_l$ is larger for a given angle of attack, while $C_{l_{\text{max}}}$ is unchanged. Thus, the flow over the effectors is neither separated nor stalled even at large deflection angles. This is verified by the fact that the pitching moment coefficient remains constant for all cases.
3.1.2 Effect of Reynolds Number

Figure 12 shows the results for the change in Reynolds number for an airfoil with a deflection of 15° and hinge location x/c = 0.7. Reynolds Number is defined as:

\[ \text{Re} = \frac{\rho V c}{\mu} \]  

Thus the chord length, c, is proportional to the Reynolds Number. The chord length of the airfoil cross-section varies from 19” (inboard) to 8” (outboard) due to taper in the wing. The Reynolds Number varies from 1 x10^6 - 2.5x10^6 across the span of the effector array at the cruise velocity of the aircraft (120 ft/s). The results show that although the Reynolds number changes considerably there is little effect on the aerodynamic performance of the airfoil. The section lift coefficient, C_l, differs only slightly near stall and the pitching moment coefficient, C_m, shows very little deviations for all cases.

3.1.3 Effect of Hinge Location

Figure 13 shows XFOIL results for airfoils with various hinge locations. Each effector has a different hinge location, because the chord of the wing changes, but the length of each effector is 4”. Thus the hinge location varies from x/c = 0.8 for the inboard effector to x/c = 0.5 for the outboard. Each of the airfoils has a 15° deflection with a Reynolds Number of 1x10^6. Since the chord length is proportional to increasing the Reynolds Number, Figure 12, shows varying the chord length will not change the results.

The results show that the outboard effectors in the array provide a greater C_l for a given angle of attack, \( \alpha \). However, this also suggests the onset of stall, defined as C_l_{max}, will occur at a lower \( \alpha \) for the outboard effectors. Therefore, although the outboard effectors are the most effective, they stall first, and the aircraft is more susceptible to wing tip stall. This tip stall of the aircraft has been has been
previously observed in the wind tunnel analysis of a sub-scale model and in the initial vehicle flight testing; the present XFOIL analysis clarifies these previous results.\textsuperscript{28} The only slight variations in pitching moment due to the hinge location occur at negative angles of attack that are unobtainable by the aircraft; it is thought that this variation does not change with hinge location.

3.1.4 Effect of Surface Geometry

The NACA 0015 airfoil with a conventional, hinged control surface and the contoured airfoil are next examined. Figure 14 shows the comparison for a 15° flap deflection at a Reynolds Number of \(1 \times 10^6\) and a hinge location of \(x/c = 0.7\). \(C_l\) and \(C_m\) of the contoured airfoil are increased compared to the conventional airfoil at any given angle of attack; therefore, there is a clear benefit in the performance of the airfoil that utilizes the contoured trailing edge. Similar results are also obtained by varying flap deflection, Reynolds Number and hinge location for the two airfoils. These results agree very well with the wind tunnel observations in the Smart Wing program (Figure 3). The wind tunnel results for the Smart Wing show an increase in lift coefficient of approximately 8%; whereas, the XFOIL analysis shows improvements of approximately 10%. The improvement in pitching moment also suggests that there are considerable improvements in the control authority of the contoured control surface.

Although the magnitude increase in \(C_l\) compare well, the pressure distributions from the XFOIL analysis differs from the wind tunnel results for the Smart Wing. The Smart Wing shows an overall increase in suction mainly due to an increase at the trailing edge location (Figure 4). However, the results from XFOIL show that the suction spike produced by the sharp transition at the flap deflection is flattened out, while there is an overall increase in the magnitude of the upper surface pressures (Figure 15 and Figure 16). This overall increase in magnitude is what accounts for the lift improvement for the contoured airfoil.
The improvement in lift is significant, and possibly could be even greater if the gap between the traditional surface and airfoil is also modeled. The gap may cause greater flow separation, and degrade the performance; whereas, the modified airfoil very closely represents the manufactured design.

In summary, the analysis shows that the effectors can be used in a wide range of conditions without degradation to the performance. The study further suggests that the array of effectors will have additional aerodynamic benefits due to the contoured geometry of the design.

3.2 CMARC Results

3.2.1 Control Power Analysis

The CMARC simulations are used to provide an inviscid, three-dimensional analysis of the UAV. The CMARC analysis reported in Ref(27) provides the baseline information for control power effectiveness of the control surfaces. The trailing edge surfaces of the UAV are designed to provide pitch and roll control; therefore, the two figures of merit used to evaluate the control power effectiveness for roll and pitch are $p_{\infty}$ and $d\alpha/d\delta_e$, respectively. The following equations are used to calculate the control power estimates:

\[
\text{Elevator Control Power} = \frac{d\alpha}{d\delta_e} = \frac{C_{m_{\alpha}}}{C_{\alpha}}
\]

\[
\text{Steady State Roll} = p_{st} = \frac{2C_{lb} V_{\infty}}{C_{ip} b} \Delta\delta_e
\]

Previous UAV research at NC State has shown good aircraft handling qualities are obtained for values of $p_{\infty}$ near 360°/s and $d\alpha/d\delta_e$ between 1 - 2.31
The control power of the effector array, predicted by CMARC analysis, ascertained that the modified control surfaces can provide adequate control of the aircraft. The analysis determined the amount of control power the effector array could provide without the assistance of the conventional surfaces. The pitch and roll authority the baseline vehicle, modified vehicle, and the effector array are shown in Figure 17 and Figure 18. The results show the vehicle outfitted with the effector array provides similar control authority to the baseline vehicle. Therefore, the modified vehicle with the effectors deployed as conventional surfaces result in handling that is similar to the baseline vehicle. A modal deflection, where the spatial distribution of tip deflections form a sine wave whose peak amplitude is 15°, is also examined. The control power is comparable to that of the baseline vehicle. Figure 17 and Figure 18 also show the control power estimates using only the effector array; it is seen that the effector array provides up to half the control power.

The effector array provides a good measure of pitch and roll authority without use of the conventional surfaces. During a flight test scenario all surfaces are used in a conventional manner for the more difficult maneuvers such as takeoff, approach and landing. Once a holding flight pattern is established at altitude, the conventional surfaces are disabled and the ability of the effector array to navigate the aircraft and perform simple maneuvers can be examined. Following the flight test the conventional surfaces can be re-engaged and the vehicle landed with a conventional control surface configuration.

3.2.2 Pressure Characterization

Figure 10 shows the CMARC panel model; in the inset of a close-up of a deflected effector is shown. The symmetry along the centerline of the aircraft simulates the presence of the sidewall in the wind tunnel tests. The CMARC model of the wing determined the pressure response to a single effectors
movement. Finally, a sensitivity matrix related the pressure response for multiple effector movements.

3.2.2.1 Single Effector Movement

CMARC yields predictions of the aerodynamic coefficients, such as lift coefficient by calculating the pressure at each panel and then integrating to find the aerodynamic coefficients. Therefore, the pressure at the panel nearest to the location of the pressure sensor can be compared to the measurement of the pressure sensor.

Figure 19 shows a plot of the CMARC pressure distribution; the inset shows effector #3 at a 10° deflection. CMARC analysis with no effector deflections provides the baseline data. The baseline data set is subtracted from the predicted pressure with the deflected effectors. The baseline data is used as a reference to determine the net change in pressure due to the displacement of the effectors. The following equation is used to quantify the pressure change, $\Delta C_p$,

$$\Delta C_p = C_{p,\text{Recorded}} - C_{p,\text{Baseline}}$$

(3.4)

The change in pressure on all sensors is measured for $+5^\circ$ and $+10^\circ$ deflections of each effector. Since the wing has a symmetric airfoil section, the pressures on the upper and lower surface for both positive and negative deflections are obtained in a single run. Figure 20, Figure 21, and Figure 22 show the pressure response for deflections of an inboard (#3), a mid-span (#6), and an outboard effector (#10). In general, the change in pressure varies linearly with deflection.

Thus, the pressure response to a single effector at any deflection angle can be predicted. It is observed that the sensor nearest to the actuated effector is most sensitive to the deflection. This sensitivity decreases for sensors further away...
from the actuated effector, the sensitivity is negligible more than three sensors away from the actuated effector.

3.2.2.2 Multiple Effector Movement

The change in pressure due to the actuation of a single effector, \( \frac{d(\Delta C_p)}{d\delta_f} \), is the slope of the linear fit shown in Figure 20-Figure 22. These slopes, sensitivity coefficients, are plotted in Figure 23 for three representative cases. They can also be summarized in a matrix of the form:

\[
A = \begin{bmatrix}
    a_{11} & a_{12} & \cdots & a_{1N} \\
    a_{21} & a_{22} & \cdots & a_{2N} \\
    \vdots & \vdots & \ddots & \vdots \\
    a_{N1} & a_{N2} & \cdots & a_{NN}
\end{bmatrix}
\]  

(3.5)

where \( a = \frac{d(\Delta C_p)}{d\delta_f} \), and the row and column numbers represent the effector and sensor numbers, respectively. The sensitivity coefficients derived in this manner from the CMARC analysis are shown in Table 1. The results in Table 1 and Figure 23 confirm that the most sensitive sensor is that which is nearest to the actuated effector. Also, the neighboring sensors equidistant to the actuated effector have approximately the same response to deflection of the effector.

The results above also suggest that the distributed actuation and sensing array could be used for failure monitoring and fault detection. Specifically, each effector configuration is uniquely related to the pressure distribution of the sensors. Therefore, for a given effector configuration, an inconsistency in the pressure distribution can be used to identify a faulty sensor. Conversely for a
measured pressure distribution, an inconsistent effector indicates the possible failure of an effector.

3.3 Wind Tunnel Results

Figure 24, shows a representative series of effector configurations in the wind tunnel that were evaluated during the testing. Three modal shapes with varying spatial frequency and a one-up-one-down configuration are shown. The purpose of the wind tunnel tests is to access the ability to characterize the pressure response due to the actuation of a single effector and then for actuation of multiple effectors.

3.3.1 Single Effector Characterization

Initially the wind tunnel experiments followed the same test matrix as the CMARC analysis. A single effector was deflected over a range of angles and the pressure response was measured. Figure 25,Figure 26 and Figure 27 show the results for a representative inboard (#3), mid-span (#6) and outboard (#10) effector moved through a ±15° degree sweep. The effectors are displaced with two degree increments to provide good resolution for the linear curve fit. The results are similar to the CMARC simulations. The change in pressure with respect to deflection of an effector is linear. The magnitudes of the pressure changes are also comparable to the CMARC analysis. As was previously observed the largest sensitivity is measured at the sensor closest to the actuated effector. The neighboring pairs of equidistant also show a similar response. The slopes of the linear fit to the data are summarized in the sensitivity matrices shown in Table 2.

The sensitivity coefficients from the CMARC analysis and the wind tunnel results are shown for three representative cases in Figure 28, Figure 29 and Figure 30. The results from the wind tunnel show that the CMARC simulations over predict
the pressures for the sensor that is closest to the actuated effector, but at the neighboring sensors the experiment and CMARC are in good agreement. The source of error could be attributed to the wake separation between the main wing and the actuated effector in the CMARC modeling. Nonetheless, the results provided a method to estimate the pressure change due to the actuation of a single effector using experimental or numerical data.

### 3.3.2 Multiple Effector Characterization

The effect of flap deflection on the change in pressure can be written in matrix form as:

\[ Ax = b \]  \hspace{1cm} (3.5)

The sensitivity coefficients \( a_{mn} \) in matrix A are given in Table 1 and Table 2 for the CMARC analysis and the wind tunnel experiment, respectively. The vectors \( x \) and \( b \) are given as

\[
\begin{align*}
\delta_{f1} \\
\delta_{f2} \\
\vdots \\
\delta_{f(N-1)} \\
\delta_{fn}
\end{align*}
\]

and

\[
\begin{align*}
\Delta C_{p1} \\
\Delta C_{p2} \\
\vdots \\
\Delta C_{p(N-1)} \\
\Delta C_{pn}
\end{align*}
\]

19
where \( x \) is a vector of flap deflections and \( b \) is a vector of change in pressure coefficient. The matrix equation therefore provides a method to combine the effects of the actuation of a single effector into the actuation of multiple effectors.

Figure 31Figure 38 show the predicted and measured pressure response for several commanded effector deflections. The prediction method is evaluated in each wing for several effector deflections including modal shapes with varying frequency, constant deflection angles, and one-up-one-down configurations. The prediction method uses Equation 3.5 to estimate the pressure response. The results show that the linear combination of the single effectors provides a reliable prediction for the multiple effector deflections for a range of effector deflections.

The above results show that the distributed effector/sensor array has the capability to meet many of the proposed mission objectives. All of the elements for closed loop control within the bandwidth limitations of the sensors and actuators are in place. Specifically, for a given effector position there is a measurable response from sensors. Therefore effectors can be commanded to a desired configuration whose resultant pressure distribution optimizes a particular flight condition, such as maximum L/D. The feedback can be potentially used for stabilization and maneuver control, disturbance rejection or upset recovery.

The overall performance of the vehicle can be improved because the effector array can be actively controlled to optimize several phases of the flight regime, such as take-off, landing and cruise.

### 3.3.3 UAV Readiness for Flight Testing
The distributed effector and sensor array has been designed, manufactured, tested and installed. Figure 39 shows UAV BWB DELTA equipped with the distributed effector and sensor array. The UAV is therefore ready to enter the
flight testing phase of the project. Final evaluations of the system which included effector calibrations and comparison of the in-flight and wind tunnel pressure monitoring systems have also been conducted.

3.3.3.1 Effector Calibrations

A servo is employed to actuate each effector. The deflection angle, for a given servo position may differ; due to slight manufacturing inconsistencies, physical taper in the wing and the varying tension in the wire linkages. Therefore, a calibration of servo position versus deflection angle was made for each effector. Figure 40 shows a graph of the calibrations for the port wing. Effectors 1-6 have a slope of equal magnitude, but opposite sign, of effectors 7-12; this is because the separate banks of servos are mounted in opposite directions (Figure 7). Table 3 summarizes the calibration results for both wings. These calibrations are incorporated into a look-up table that may be used in a flight computer system to command an effector to a specific deflection angle.

3.3.3.2 Comparison of Pressure Systems

Figure 41 shows a comparison of the measured pressures using the two pressure monitoring systems used during the wind tunnel testing. The Scanivalve™ system is a mechanically multiplexed, pressure system permanently mounted the wind tunnel; the ESP module is a compact lightweight, electronically multiplexed system that will ultimately be used for in-flight pressure measurement. The results show that both systems provide identical results. Thus, the ESP module is suitable to be used as the pressure monitoring system during the flight testing portion of the project.
4. CONCLUDING REMARKS

4.1 Summary of Results

This study examines the effectiveness of multi-axis control of a UAV using a distributed actuation and sensing array that was designed, manufactured and analyzed. XFOIL and CMARC are used to computationally evaluate the design, and then wind tunnel tests are used to experimentally validate the design.

XFOIL provides a two-dimensional numerical analysis of the effects of flap deflection, Reynolds Number, and hinge location. This analysis is used to demonstrate the performance benefits of a contoured surface in the design of the effectors. The distributed array consists of 24 effectors that is 12 on each wing. The resulting effector is comprised of two plates of spring steel having dimensions 4" (chord) x 1.5" (span) x 0.007" (thickness). The effectors are actuated by a hobby servo via antagonizing pull-pull linkages. The pressure sensors, centered at the base of each effector, are located on the upper surface of the wing. An array of 24 pressure sensors provides feedback information for the system.

Subsequent three-dimensional analysis using CMARC provides comparisons of the control authority for the baseline vehicle equipped with conventional surfaces to the control authority of the modified vehicle equipped with the effector array. The modified vehicle has comparable control authority in addition to the advantages of distributed effectors. These advantages include fault tolerance, failure monitoring, and aeroelastic tailoring.

Wind tunnel testing provides an experimental evaluation of the performance of the effector array. The measured effects of the deflections compare well with the
CMARC simulations. The simulated and measured pressures, in response to the deflections of a single effector, are used to develop a simple but accurate method to determine the pressure distribution that results from deflections of multiple effectors.

4.2 Continuing Research
At the time of writing this thesis, wind tunnel testing of the fully equipped UAV is underway at the NASA-Langley 12' Wind Tunnel. The purpose of the test is to access the static and dynamic performance of the actuation and sensing suite. Preliminary results are encouraging and indicate that flight testing would be beneficial.

4.3 Recommendations for Future Work
Following the wind tunnel testing at NASA the UAV will be readied for flight testing. The present study and the wind tunnel tests at NASA provide a experimental and numerical database that can be used as the basis for multiple controller designs. The envisaged flight test plan includes the demonstration of closed loop, multi-axis control using the distributed effector and sensor arrays.
