Since its founding, NASA has been dedicated to the advancement of aeronautics and space science. The NASA Scientific and Technical Information (STI) Program Office plays a key part in helping NASA maintain this important role.

The NASA STI Program Office is operated by Langley Research Center, the lead center for NASA’s scientific and technical information. The NASA STI Program Office provides access to the NASA STI Database, the largest collection of aeronautical and space science STI in the world. The Program Office is also NASA’s institutional mechanism for disseminating the results of its research and development activities. These results are published by NASA in the NASA STI Report Series, which includes the following report types:

TECHNICAL PUBLICATION. Reports of completed research or a major significant phase of research that present the results of NASA programs and include extensive data or theoretical analysis. Includes compilations of significant scientific and technical data and information deemed to be of continuing reference value. NASA counterpart of peer-reviewed formal professional papers, but having less stringent limitations on manuscript length and extent of graphic presentations.

TECHNICAL MEMORANDUM. Scientific and technical findings that are preliminary or of specialized interest, e.g., quick release reports, working papers, and bibliographies that contain minimal annotation. Does not contain extensive analysis.

CONTRACTOR REPORT. Scientific and technical findings by NASA-sponsored contractors and grantees.

CONFERENCE PUBLICATION. Collected papers from scientific and technical conferences, symposia, seminars, or other meetings sponsored or co-sponsored by NASA.

SPECIAL PUBLICATION. Scientific, technical, or historical information from NASA programs, projects, and missions, often concerned with subjects having substantial public interest.

TECHNICAL TRANSLATION. English-language translations of foreign scientific and technical material pertinent to NASA’s mission.

Specialized services that complement the STI Program Office’s diverse offerings include creating custom thesauri, building customized databases, organizing and publishing research results ... even providing videos.

For more information about the NASA STI Program Office, see the following:

Abstract

A thermodynamically consistent damage model for the simulation of progressive delamination under variable mode ratio is presented. The model is formulated in the context of the Damage Mechanics. The constitutive equation that results from the definition of the free energy as a function of a damage variable is used to model the initiation and propagation of delamination. A new delamination initiation criterion is developed to assure that the formulation can account for changes in the loading mode in a thermodynamically consistent way. The formulation proposed accounts for crack closure effects avoiding interfacial penetration of two adjacent layers after complete decohesion. The model is implemented in a finite element formulation. The numerical predictions given by the model are compared with experimental results.

1 Introduction

Delamination is one of the most common types of damage in laminated fibre-reinforced composites due to their relatively weak interlaminar strengths. Delamination may arise under various circumstances, such as in the case of transverse concentrated loads caused by low velocity impacts.

Structural collapse in a composite structure is often caused by the evolution of different types of damages created in a local zone of the structure. The particular damage modes depend upon loading, lay-up and stacking sequence. Delamination is often a significant contributor to the collapse of a structure
Moore et al. [2] justify the need to account for delamination from the point of view of Fracture Mechanics: the energy release rates necessary for failure of a composite part from intralaminar and interlaminar damage were computed and the results showed that the lowest energy release rate obtained was for delamination.

When other material non-linearities can be neglected, methods based on Linear Elastic Fracture Mechanics (LEFM) have been proven to be effective in predicting delamination growth. However, LEFM cannot be applied without an initial crack. In many situations, stress-based methods have been applied to predict the initiation of delaminations, and after the delamination onset, Fracture Mechanics can be used to describe delamination growth [3]-[4]. Techniques such as virtual crack closure technique (VCCT) [5]-[9], J-integral method [10], virtual crack extension [11] and stiffness derivative [12] have often been used. These techniques have in common that the delamination is assumed to propagate when the associated energy release rate is greater than or equal to a critical value [13]. However, difficulties are also encountered when these techniques are implemented using finite element codes. The calculation of fracture parameters, e.g. stress intensity factors or energy release rates, requires nodal variable and topological information from the nodes ahead and behind the crack front. Such calculations can be done with some effort for a stationary crack, but can be extremely difficult when progressive crack propagation is involved.

Another approach to the numerical simulation of the delamination can be developed within the framework of Damage Mechanics. Models formulated using Damage Mechanics are based on the concept of the cohesive crack model: a cohesive damage zone or softening plasticity is developed near the crack front. The origin of the cohesive crack model goes back to Dugdale [14] who introduced the concept that stresses in the material are limited by the yield stress and that a thin plastic is generated in front of the notch. Barenblatt [15] introduced cohesive forces on a molecular scale in order to solve the problem of equilibrium in elastic bodies with cracks. Hillerborg et al. [16] proposed a model similar to the Barenblatt model, but where the concept of tensile strength was introduced. Hillerborg’s model allowed for existing cracks to grow and, even more importantly, also allowed for the initiation of new cracks.

Cohesive damage zone models relate tractions to displacement jump at an interface where a crack may occur. Damage initiation is related to the interfacial strength, i.e., the maximum traction on the traction-displacement jump curve. When the area under the traction/displacement jump curve is equal to the fracture toughness, the traction is reduced to zero and new crack surface formed. The advantages of cohesive zone models are their simplicity and the unification of crack initiation and growth within one model. Moreover, cohesive zone formulations can also be easily implemented in finite element codes.
using decohesion elements [17]-[25].

In the formulation of the cohesive models, it is important to control the energy dissipation during delamination growth in order to avoid the restoration of the cohesive state, i.e., it is necessary to assure that the model satisfies the Clausius-Duhem inequality. There are some models in the literature that can be used under mixed-mode conditions [21],[23]-[24], [29]-[34], but some of them do not satisfy the Clausius-Duhem inequality under variable-mode loading situation.

A damage model for the simulation of delamination under variable-mode is presented in this paper. A new delamination initiation criterion is developed from the expression of the critical energy release rate for delamination propagation under mixed-mode loading presented in [35]. The model is implemented into the commercial finite element code ABAQUS by means of a user-written decohesion element.

This paper is structured as follows: first, the formulation of the delamination onset and growth model is presented. Afterward, the delamination damage model is formulated and the initiation and propagation surfaces are defined. The finite element discretization of the boundary value problem is based on the variational formulation of the local form of momentum balance. Finally, the numerical predictions are compared with experimental results.

2 Model for delamination onset and propagation

The boundary value problem, the kinematic equations, and the constitutive relations are presented for the formulation of the model for delamination onset and delamination propagation.

2.1 Boundary value problem

Consider a domain $\Omega$, as shown in figure 1(a), containing a crack $\Gamma_c$. The part of the crack on which a cohesive law is active is denoted by $\Gamma_{coh}$ and is called the fracture process zone (FPZ).

Prescribed tractions, $F_i$, are imposed on the boundary $\Gamma_F$, whereas prescribed displacements are imposed on $\Gamma_u$. The stress field inside the domain, $\sigma_{ij}$, is related to the external loading and the closing tractions $\tau_j^+, \tau_j^-$ in the cohesive zone through the equilibrium equations:

$$\sigma_{ij,j} = 0 \text{ on } \Omega$$ (1)
2.2 Kinematics of the interfacial surface

To develop the necessary kinematic relationships, consider the crack $\Gamma_c$ shown in Figure 1(a) part of a material discontinuity, $\Gamma_d$, which divides the domain $\Omega$ into two parts, $\Omega_+$ and $\Omega_-$ (Figure 1(b)).

The displacement jump $[u_i]$ across the material discontinuity $\Gamma_d$ can be written as:

$$[u_i] = u_i^+ - u_i^-$$

where $u_i^\pm$ denotes the displacement of the points on the surface of the material discontinuity $\Gamma_d$ of the part $\Omega_\pm$ of the domain.

The fundamental problem introduced by the interfacial surface $\Gamma_d$ is how to express the virtual displacement jumps associated to the surfaces $\Gamma_d^\pm$ as a function of the virtual displacements. Consider a three-dimensional space with Cartesian coordinates $X_i$, $i = 1, 2, 3$. Let the Cartesian coordinates $x_i^\pm$ describe the deformation of the upper and lower surfaces $\Gamma_d^\pm$ in the deformed configuration. Any material point on $\Gamma_d^\pm$ in the deformed configuration is related to its undeformed configuration through:

$$x_i^\pm = X_i + u_i^\pm$$

where $u_i^\pm$ are displacements quantities with respect to the fixed Cartesian coordinate system. Then, the coordinates $\bar{x}_i$ of the midsurface can be written as:

$$\bar{x}_i = X_i + \frac{1}{2} (u_i^+ + u_i^-)$$
The components of the displacement jump vector are evaluated at the mid-surface $\Gamma_d$, which is coincident with $\Gamma_d$ in the undeformed configuration (see figure 2). The midsurface coordinate gradients define the components of the two vectors, $v_{\eta_i}$ and $v_{\xi_i}$, that define the tangential plane at a given point, $\bar{P}$:

$$v_{\eta_i} = \bar{x}_{i,\eta}$$

$$v_{\xi_i} = \bar{x}_{i,\xi}$$

where $\eta, \xi$ are curvilinear coordinates on the surface $\Gamma_d$. Although $v_{\eta_i}$ and $v_{\xi_i}$ are generally not orthogonal to each other, their vector product defines a surface normal. Therefore, the local normal coordinate vector is obtained as:

$$v_n = v_{\xi} \times v_{\eta} \| v_{\xi} \times v_{\eta} \|^{-1}$$

The tangential coordinates are then obtained as:

$$v_s = v_{\xi} \| v_{\xi} \|^{-1}$$

$$v_t = v_n \times v_s$$

The components of $v_n, v_s$ and $v_t$ represent the direction cosines of the local coordinate system in the global coordinate system at a material point $\bar{P} \in \Gamma_d$. The director cosines define the following rotation tensor $\Theta_{mi}$, expressed in Voigt notation as:

$$\Theta = [v_n, v_s, v_t]$$

$\Theta$ is orthogonal and relates the local coordinate system to the fixed coordinate system. Using the rotation tensor, the normal and tangential components of the displacement jump tensor expressed in terms of the displacement field in
global coordinates are:
\[ \Delta_m = \Theta_{mi} [u_i] \] (13)
\[ \Delta_m \] is the displacement jump tensor in the local coordinate system.

The deformed differential surface area of the midsurface \( d\bar{\Gamma}_d \) is expressed in the form:
\[ d\bar{\Gamma}_d = \| \mathbf{v}_\xi \times \mathbf{v}_\eta \| d\Gamma_d^0 = J d\Gamma_d^0 \] (14)
where \( d\Gamma_d^0 \) is the differential undeformed surface area.

### 2.3 Constitutive laws

A constitutive law relating the cohesive tractions, \( \tau_j \), to the displacement jump in the local coordinates, \( \Delta_i \), is required for modelling the constitutive behaviour of the material discontinuity. The constitutive laws in the material discontinuity may be formally written:
\[ \tau_j = \tau (\Delta_i) \] (15)
\[ \dot{\tau}_j = D^{\text{tan}}_{ji} \dot{\Delta}_i \] (16)
where \( D^{\text{tan}}_{ji} \) is the constitutive tangent stiffness tensor.

A new constitutive model relating the displacement jumps to the tractions, and based on Damage Mechanics is proposed.

The delamination model proposed follows the general formulation of Continuum Damage Models proposed by Simo and Ju [36]-[37] and Mazars [38].

The free energy per unit volume of the interface is defined as:
\[ \psi (\Delta, d) = (1 - d) \psi^0 (\Delta) \] (17)
where \( d \) is the damage variable and \( \psi^0 \) is a convex function in the displacement jump space defined as:
\[ \psi^0 (\Delta) = \frac{1}{2} \Delta_i D^0_{ij} \Delta_j \] (18)

Negative values of \( \Delta_3 \) do not have any physical meaning because interpenetration is prevented by contact. Therefore negative values of \( \Delta_3 \) should not have any influence in the variation of the free energy of the interface. Thus, a modification of equation (17) is proposed to prevent interfacial penetration of the two adjacent layers after complete decohesion. The expression for the free energy per unit volume proposed is:
\[ \psi (\Delta, d) = (1 - d) \psi^0 (\Delta_i) - d \psi^0 \left( \delta_{3i} (\Delta_{3i}) \right) \] (19)
where $\langle \cdot \rangle$ is the MacAuley bracket defined as $\langle x \rangle = \frac{1}{2} (x + |x|)$ and $\delta_{ij}$ is the Kronecker delta. The constitutive equation for the interface is obtained by differentiating the free energy with the displacement jumps:

$$\tau_i = \frac{\partial \psi}{\partial \Delta_i} = (1 - d) D_{ij}^0 \Delta_j - d D_{ij}^0 \delta_{3j} \langle -\Delta_3 \rangle$$  \hspace{1cm} (20)

In the present model, the initial stiffness tensor, $D_{ij}^0$, is defined as:

$$D_{ij}^0 = \delta_{ij} K$$  \hspace{1cm} (21)

where the scalar parameter $K$ is a penalty stiffness. In the expanded form, the constitutive equation can be written in Voigt notation as:

$$\tau = \begin{bmatrix} \tau_1 \\ \tau_2 \\ \tau_3 \end{bmatrix} = (1 - d) K \begin{bmatrix} \Delta_1 \\ \Delta_2 \\ \Delta_3 \end{bmatrix} - d K \begin{bmatrix} 0 \\ 0 \\ \langle -\Delta_3 \rangle \end{bmatrix}$$ \hspace{1cm} (22)

The energy dissipation during damage evolution, $\Xi$, represented in Figure 3 for single-mode loading, can be obtained from:

$$\Xi = - \frac{\partial \psi}{\partial d} \geq 0$$ \hspace{1cm} (23)

The model defined by equation (20) is fully determined if the value of the damage variable $d$ can be evaluated at every time step of the deformation process. For that purpose, it is necessary to define a suitable norm of the displacement jump tensor, a damage criterion, and a damage evolution law, as will be described in the following sections.

![Fig. 3. Energy dissipation during damage evolution](image-url)
2.3.1 Norm of the displacement jump tensor

The norm of the displacement jump tensor is denoted as \( \lambda \) and is also called equivalent displacement jump norm. It is used to compare different stages of the displacement jump state so that it is possible to define such concepts as ‘loading’, ‘unloading’ and ‘reloading’. The equivalent displacement jump is a non-negative and continuous function, defined as:

\[
\lambda = \sqrt{(\Delta_3)^2 + (\Delta_{\text{shear}})^2}
\]

(24)

where \( \Delta_3 \) is the displacement jump in mode I, i.e., normal to midplane, and \( \Delta_{\text{shear}} \) is the euclidean norm of the displacement jump in mode II and in mode III:

\[
\Delta_{\text{shear}} = \sqrt{(\Delta_1)^2 + (\Delta_2)^2}
\]

(25)

2.3.2 Damage criterion

The damage criterion is formulated in the displacement jump space. The form of this criterion is:

\[
F\left( \lambda^t, r^t \right) := \lambda^t - r^t \leq 0 \quad \forall t \geq 0
\]

(26)

where \( t \) indicates the actual time and \( r^t \) is the damage threshold for the current time. If \( r^0 \) denotes the initial damage threshold, then \( r^t \geq r^0 \) at every point in time. Damage initiation is produced when the displacement jump norm, \( \lambda \), exceeds the initial damage threshold, \( r^0 \), which is a material property.

A fully equivalent expression for equation (26) that is more convenient for algorithmic treatment is [39]:

\[
\tilde{F}\left( \lambda^t, r^t \right) := G\left( \lambda^t \right) - G\left( r^t \right) \leq 0 \quad \forall t \geq 0
\]

(27)

where \( G(\cdot) \) is a suitable monotonic scalar function ranging from 0 to 1. \( G(\cdot) \) will define the evolution of the damage value, and will be presented in the next section.

2.3.3 Damage evolution law

The evolution laws for the damage threshold and the damage variable must be defined in the damage model. These laws are defined by the rate expressions:

\[
\dot{\lambda} = \mu
\]

(28)

\[
\dot{d} = \mu \frac{\partial F\left( \lambda, r \right)}{\partial \lambda} = \mu \frac{\partial G\left( \lambda \right)}{\partial \lambda}
\]

(29)
where \( \dot{\mu} \) is a damage consistency parameter used to define loading/unloading conditions according to the Kuhn-Tucker relations:

\[
\dot{\mu} \geq 0 \quad ; \quad \vec{F}(\lambda^t, r^t) \leq 0 \quad ; \quad \dot{\mu}\vec{F}(\lambda^t, r^t) = 0 \quad (30)
\]

From the previous equations it is easy to prove \[36\] that the evolution of the internal variables may be explicitly integrated to render:

\[
r^t = \max \left\{ r^0, \max_s \lambda^s \right\} \quad 0 \leq s \leq t
\]

\[
d^t = G(r^t) \quad (32)
\]

which fully describes evolution of the internal variables for any loading/unloading/reloading situation. The scalar function \( G(\cdot) \) defines the evolution of the damage value. For a given mixed-mode ratio, \( \beta \), the function proposed here is defined as,

\[
G(\lambda) = \frac{\Delta^f (\lambda - \Delta^0)}{\lambda (\Delta^f - \Delta^0)} \quad (33)
\]

Equation (33) defines the damage evolution law by means of a bilinear constitutive equation (see Figure 4), where \( \Delta^0 \) is the onset displacement jump and it is equal to the initial damage threshold \( r^0 \). The initial damage threshold is obtained from the formulation of the initial damage surface or initial damage criterion. \( \Delta^f \) is the final displacement jump and it is obtained from the formulation of the propagation surface or propagation criterion.

![Figure 4](image)

Fig. 4. A bilinear constitutive equation for the decohesion element for a mixed mode loading situation

It is therefore necessary to establish the delamination onset and propagation surfaces for the complete definition of the damage model. Delamination onset and propagation surfaces and the damage evolution law fully define the constitutive equations.
The constitutive equations for the interfacial surface are normally developed in a phenomenological way, i.e., satisfying empirical relations that are obtained using experimental results. There are several types of constitutive equations used in decohesion elements: Tvergaard and Hutchinson [40] propose a trapezoidal law, Cui and Wisnom [41] a perfectly plastic rule, Needleman first presented a polynomial law, [27], and later an exponential law [28]. Goyal et al.[42] adopted Needleman’s exponential law to account for load reversal without material healing.

In this paper the law used within the decohesion elements is a bilinear law [21],[24],[43]. The bilinear law is the most commonly used cohesive law due to its simplicity. One drawback of the bilinear law is that the traction-displacement jump relation is discontinuous at its maximum. The discontinuities in the traction-displacement jump relation can be avoided using continuous functions. However, even for such continuous functions, the discontinuity is unavoidable when modeling loading-unloading cycles.

For a given mixed-mode ratio, \( \beta \), defined as:

\[
\beta = \frac{\Delta_{\text{shear}}}{\Delta_{\text{shear}} + \langle \Delta_\theta \rangle}
\]  

(34)

the bilinear constitutive equation is defined by a penalty parameter, \( K \), the damage value, \( d \), the mixed-mode damage initiation, \( \Delta^0 \) and the total decohesion parameter, \( \Delta^f \). These last two values are given by the formulation of the onset and the propagation criterion which takes into account the interaction between different modes and their value depends on the mixed-mode ratio \( \beta \). The penalty parameter \( K \) assures a stiff connection between two neighboring layers before delamination initiation. The penalty parameter should be large enough to provide a reasonable stiffness but small enough to avoid numerical problems, such as spurious tractions oscillations [44], in a finite element analysis. Daudeville et al. [45] have proposed the definition of the penalty stiffness as a function of the interface thickness, \( t \), and elastic moduli of the interface. Zou et al. [4],[46] have proposed a value for the penalty parameter between \( 10^5 \) and \( 10^7 \) times the value of the interfacial strength per unit length. Camanho and Dávila [24],[47] successfully used a value of \( 10^6 N/mm^3 \), which is smaller than the values proposed by Daudeville et al. [45] and Zou et al. [4],[46].

**Propagation criterion**

The criterion used to predict delamination propagation under mixed-mode loading conditions is usually established in terms of the energy release rate and fracture toughness. It is assumed that when the energy release rate, \( G \), exceeds a critical value, the critical energy release rate \( G_c \), delamination will grow.
The most widely used criterion to predict delamination propagation under mixed-mode loading, the “power law criterion” is normally established in terms of a linear or quadratic interaction between the energy release rates \[48\]. However, Camanho et al. \[24\] shown that using the expression proposed by Benzeggagh and Kenane \[35\] for the critical energy release rate for a mixed-mode ratio is more accurate for epoxy composites. Using the expression by Benzeggagh and Kenane in \[35\], the propagation criterion can be written as:

\[
G = G_{IC} + (G_{IIc} - G_{IC}) \left( \frac{G_{shear}}{G_T} \right)^\eta
\]  

(35)

where \( G = G_I + G_{shear} \) is the energy release rate under mixed-mode loading and \( G_{shear} = G_{II} + G_{III} \) is the energy release rate for shear loading proposed by Li \[49\],[50\].

The propagation surface in the displacement jump space is defined through the final displacements, which are defined from the pure mode fracture toughness \( G_{IC}, G_{IIC}, G_{IIIc} \) and considering that the area under the traction-displacement jump curves is equal to the corresponding fracture toughness, i.e.:

\[
G_C = \frac{1}{2} K \Delta^0 \Delta^f
\]  

(36)

For a given mixed-mode ratio, \( \beta \), the energy release rates corresponding to total decohesion are obtained from:

\[
G_I = \frac{1}{2} K \Delta^0_3(\beta) \Delta^f_3(\beta)
\]  

(37)

\[
G_{shear} = \frac{1}{2} K \Delta^0_{shear}(\beta) \Delta^f_{shear}(\beta)
\]  

(38)

where \( \Delta^0_{shear}(\beta) \) and \( \Delta^0_3(\beta) \) are respectively the shear and normal displacement jump corresponding to the onset of softening under mixed-mode loading, and \( \Delta^f_{shear}(\beta) \) and \( \Delta^f_3(\beta) \) are respectively the shear and normal displacement jump corresponding to the total decohesion under mixed-mode loading.

From (34):

\[
\Delta^0_{shear}(\beta) = \Delta^0_3(\beta) \frac{\beta}{\beta + 1}
\]  

(39)

\[
\Delta^f_{shear}(\beta) = \Delta^f_3(\beta) \frac{\beta}{\beta + 1}
\]  

(40)

Using equations (39) and (40) in (37) and (38) the ratio between \( \frac{G_{shear}}{G_T} \) can be established in terms of \( \beta \):

\[
\frac{G_{shear}}{G_T} = \frac{\beta^2}{1 + 2\beta^2 - 2\beta}
\]  

(41)
Since the ratio \( \frac{G_{\text{shear}}}{G_T} \) is only a function of the mixed-mode ratio \( \beta \), henceforward this ratio is named as \( B \):

\[
B = \frac{G_{\text{shear}}}{G_T} \tag{42}
\]

Using equation (36), (41) and (42) in equation (35) the propagation criterion is obtained in the displacement jump space as:

\[
\Delta f = \frac{\Delta_0 \Delta_3^0 + \left( \Delta_0^0 \Delta_{\text{shear}} - \Delta_3^0 \Delta_3^0 \right) [B]^{\eta}}{\Delta_0^0} \tag{43}
\]

**Initial damage surface**

Under pure mode I, mode II or mode III loading, delamination onset occurs when the corresponding interlaminar traction exceeds its respective maximum interfacial strength, \( \tau_0^0 \), \( \tau_0^2 \), \( \tau_0^1 \). Under mixed-mode loading, an interaction between modes must be taken into account. Few models take into account the interaction of the traction components in the prediction of damage onset. The models that account for the interaction of the traction components are usually based on Ye’s criterion [51], using a quadratic interaction between modes:

\[
\frac{(\tau_3)}{\tau_3^0}^2 + \frac{(\tau_2)}{\tau_2^0}^2 + \frac{(\tau_1)}{\tau_1^0}^2 = 1 \tag{44}
\]

However, experimental data for the initiation of delamination under mixed-mode is not readily available and consequently, failure criterion that can predict the initiation have not been fully validated.

The criterion for propagation is often formulated independently of the criterion for initiation. In this paper, a link between propagation and initiation is proposed. Since delamination is a fracture process, the initiation criterion proposed in this paper evolves from the propagation criterion and the damage evolution law. The isodamage surface for a damage value equal to 1 corresponds to the propagation surface obtained from equation (35). Then, the isodamage surface for a damage value equal to 0 is the initial damage surface. With these assumptions, the criterion for delamination initiation proposed here is:

\[
\left( \tau_0^0 \right)^2 = (\tau_3^0)^2 + (\tau_1^0)^2 + (\tau_2^0)^2 = (\tau_3^0)^2 + \left( (\tau_{\text{shear}}^0)^2 - (\tau_3^0)^2 \right) [B]^{\eta} \tag{45}
\]

In the displacement jump space, the criterion becomes:

\[
\left( \Delta_0^0 \right)^2 = (\Delta_3^0)^2 + (\Delta_1^0)^2 + (\Delta_2^0)^2 = (\Delta_3^0)^2 + \left( (\Delta_{\text{shear}}^0)^2 - (\Delta_3^0)^2 \right) [B]^{\eta} \tag{46}
\]
The initiation criterion developed here and summarized by equation (45) is compared with Ye’s criterion and with a maximum traction criterion, which do not take into account mode interaction. The surfaces obtained by the different criterions are represented in Figure 5. The values predicted by the new criterion are very close to Ye’s criterion, that has been successfully used in previous investigations [24].

![Figure 5. Comparison between Ye’s criterion, a maximum traction criterion and the new proposed criterion](image)

The formulation presented assures a smooth transition for all mixed-mode ratios between the initial damage surface to the propagation surface through damage evolution. In Figure 6 it is represented the evolution of the damage surface from the damage initiation surface to the propagation surface for positive values of displacement jumps.

### 2.4 Formulation of the constitutive tangent tensor

According to equation (16), the constitutive tangent tensor needs to be defined for the formulation of the constitutive laws in the material discontinuity and for the later numerical implementation of the proposed model. The constitutive tangent tensor is obtained from the differentiation of the secant equation (20):

\[
\dot{\tau}_i = D_{ij} \dot{\Delta}_j - \delta_{ij} K \left[ 1 + \bar{\delta}_{ij} \frac{\Delta_j}{\Delta_j} \right] \Delta_j \dot{d}
\]  

(47)
where \( D_{ij} \) is defined as:

\[
D_{ij} = \tilde{\delta}_{ij} K \left[ 1 - d \left( 1 + \tilde{\delta}_{3j} \frac{(-\Delta_j)}{\Delta_j} \right) \right]
\]  

(48)

The evolution of the damage variable \( d \) only occurs for loading situations. Then, the evolution of the damage variable can be written as:

\[
\dot{d} = \begin{cases} 
\dot{G}(\lambda) = \frac{\partial G(\lambda)}{\partial \lambda} \dot{\lambda}, & r < \lambda < \Delta^f \\
0, & r > \lambda \text{ or } \Delta^f < \lambda 
\end{cases}
\]  

(49)

where the variation of the function \( G \) is obtained assuming that the variation of the final displacement jump \( \Delta^f \) and the onset displacement jump \( \Delta^0 \) with the mixed-mode ratio \( \beta \) are not significant for the time increment taken:

\[
\frac{\partial G(\lambda)}{\partial \lambda} = \frac{\Delta^f \Delta^0}{\Delta^f - \Delta^0} \frac{1}{\lambda^2}
\]  

(50)

The evolution of the displacement norm is obtained from equation (24):

\[
\dot{\lambda} = \frac{\partial \lambda}{\partial \Delta_k} \dot{\Delta}_k = \frac{\Delta_k}{\lambda} \left( 1 + \tilde{\delta}_{3k} \frac{(-\Delta_k)}{\Delta_k} \right) \dot{\Delta}_k
\]  

(51)

Using equations (49) through (51), equation (47) can be written as:

\[
\dot{\tau}_i = D_{ij} \dot{\Delta}_j
\]  

(52)
\[ D_{ij}^{\text{tan}} = \begin{cases} 
D_{ij} - K \left[ 1 + \delta_{ij} \left( \frac{-\Delta_i}{\Delta_j} \right) \right] \left[ 1 + \delta_{ji} \left( \frac{-\Delta_j}{\Delta_i} \right) \right] H \Delta_i \Delta_j & , r < \lambda < \Delta f \\
D_{ij} & , r > \lambda \text{ or } \Delta f < \lambda 
\end{cases} \] (53)

where \( H \) is a scalar value given by:

\[ H = \frac{\Delta f \Delta^0}{\Delta f - \Delta^0} \frac{1}{\lambda^3} \] (54)

3 Finite element discretization - computational model

To transform the strong form of the boundary value problem into a weak form better suited for finite element computations, the displacement \( u_i \) must belong to the set \( U \) of the kinematically admissible displacement fields which allows for discontinuous displacements across the boundary \( \Gamma_d \) of the delamination. The weak form of the equilibrium equation is [52]:

\[ \int_{\Omega} \sigma_{ij} \delta \varepsilon_{ij} d\Omega + \int_{\Gamma_d} \tau_i \delta \Delta_m J d\Gamma_d^0 = \int_{\Gamma_f} F_i \delta v_i d\Gamma + \int_{\Omega} \rho b_i \delta v_i d\Omega \quad \forall v_i \in U \] (55)

where \( b_i \) are the body forces, \( F_i \) are surface forces, and equation (14) has been used to relate the initial and the deformed midsurface of the material discontinuity.

The discretization of the domain has been performed by the discretization of the whole domain \( \Omega \) with standard volume elements. However, the surfaces surrounding the potential delamination \( \Gamma_d \) are discretized with decohesion elements [24]. The discretized formulation is divided in the two domains considering no formal coupling between the continuous and the discontinuous parts of the deformation in the expression for the free energy of the interface [53]. Since the decohesion elements used have zero thickness, the body forces are neglected in these elements. Moreover, it is assumed that no external surface loads are applied. Therefore, the weak form of the internal virtual work for the elements in the surfaces surrounding the potential delaminations can be written as:

\[ \int_{\Gamma_d} \tau_i \delta \Delta_m J d\Gamma_d^0 = 0 \] (56)

The displacements and displacement gradients for the decohesion elements are approximated as:

\[ u_i \big|_{\Omega_e} = N_K^e q_{K_i}^e \] (57)

\[ \left[ u_i \right] \big|_{\Omega_e} = \overline{N}_K^e q_{K_i}^e \] (58)
where

\[
\mathbf{N}_K = \begin{cases} 
\mathbf{N}_K^e & K \in \Gamma_d^+ \\
-\mathbf{N}_K^e & K \in \Gamma_d^-
\end{cases}
\]  

(59)

where, \(q_{Ki}^e\) is the displacement in the \(i\) direction of the \(K\) node of the element, \(N_K^e\) are standard Lagrangian shape functions [52]. \(\mathbf{N}_K\) are standard Lagrangian shape functions defined for the decohesion elements [24].

Using equation (58) in equation (56) the weak form of the internal virtual work at current time \(t \in \mathbb{R}^+\), is given by:

\[
\int_{\Gamma_d} \tau_i \hat{B}_{im,K} \delta q_{Ki} J d\Gamma_d^0 = 0 \quad (60)
\]

where \(\hat{B}_{miK}\) is the discrete operator that relates the displacement jump in local coordinates to nodal displacements,

\[
\delta \Delta_m = \hat{B}_{miK} \delta q_{Ki} \quad (61)
\]

The system of equations given by equation (60) forms the basis for the assumed displacement finite element procedure.

### 3.1 Discretization of the interfacial surface

#### 3.1.1 Element kinematics

According to equation (57), the displacement field, \(u_i\), and the undeformed material coordinate, \(X_i\), associated to the surfaces \(\Gamma_{dz}\) are interpolated as follows:

\[
u \pm_i = N_K q_i^\pm
\]

(62)

\[
X \pm_i = N_K p_i^\pm
\]

(63)

where \(q_{Ki}^e\) are the nodal displacement vector and \(p_{Ki}^\pm\) are the undeformed material nodal coordinate vector. Note that the values of \(p_{Ki}^-\) and \(p_{Ki}^+\) can be different in the case that an initial crack exists. Using these equations, the material coordinates of the interfacial midsurface are:

\[
\bar{x}_i = \frac{1}{2} N_{K_i} \left( p_{Ki}^+ + p_{Ki}^- + q_{Ki}^+ + q_{Ki}^- \right)
\]

(64)

The components of the two vectors that define the tangential plane can be written as:

\[
v_\eta_i = \bar{x}_i,\eta = N_{K_i,\eta} \frac{1}{2} \left( p_{Ki}^+ + p_{Ki}^- + q_{Ki}^+ + q_{Ki}^- \right)
\]

(65)

\[
v_\xi_i = \bar{x}_i,\xi = N_{K_i,\xi} \frac{1}{2} \left( p_{Ki}^+ + p_{Ki}^- + q_{Ki}^+ + q_{Ki}^- \right)
\]

(66)
Using (58) and (12), the displacement jump can then be obtained in local coordinates as:

$$\Delta_m = \Theta_{im} \bar{N}_k q_{Ki} = \bar{B}_{imK} q_{Ki}$$  \hspace{1cm} (67)

### 3.1.2 Element internal force vector and tangent stiffness matrix

The internal force vector of the interface element obtained from equation (60) is given by:

$$f_{Ki} = \int_{\Gamma_d} \tau_i \hat{B}_{imK} J d\Gamma_0$$  \hspace{1cm} (68)

where $\hat{B}_{imK}$ can be written as:

$$\hat{B}_{imK} = \frac{\delta \Delta_m}{\delta q_{Ki}} = \frac{\partial B_{jmP}}{\partial q_{Ki}} q_{Pj} + \bar{B}_{imK}$$  \hspace{1cm} (69)

The softening nature of the decohesion element constitutive equation causes difficulties in obtaining a converged solution for the non-linear problem. Numerical algorithms such as Newton-Raphson method are used to solve the nonlinear problem. Therefore, the tangent stiffness matrix must be defined.

The tangent stiffness matrix stems from the linearization of the internal force vector and it is obtained using Taylor’s series expansion about the approximation $q_{Ki}$ [25]. The tangent stiffness matrix, $K_{KiZv}$, for the decohesion element is:

$$K_{KiZv} = \frac{\partial f_{Ki}}{\partial q_{Zv}} = \int_{\Gamma_d} \frac{d\tau_i}{dq_{Zv}} \hat{B}_{imK} J d\Gamma_0 + \int_{\Gamma_d} \frac{d\hat{B}_{imK}}{dq_{Zv}} \tau_i J d\Gamma_0 + \int_{\Gamma_d} \frac{dJ}{dq_{Zv}} \tau_i \hat{B}_{imK} d\Gamma_0$$  \hspace{1cm} (70)

The computation of the tangent stiffness matrix is intensive and a very accurate expression is not required. Therefore, the second and the third term in the R.H.S of equation (70) are neglected. Thus, the approximate tangent stiffness matrix is:

$$K_{KiZv} \approx \int_{\Gamma_d} \frac{d\tau_i}{dq_{Zv}} \hat{B}_{imK} J d\Gamma_0 = \int_{\Gamma_d} \hat{B}_{vijZ} D^\text{tan}_{ij} \hat{B}_{imK} J d\Gamma_0$$  \hspace{1cm} (71)

where $D^\text{tan}_{ij}$ is the material tangent stiffness matrix, or constitutive tangent tensor used to define the tangent stiffness matrix. The constitutive tangent tensor is defined in 2.4.

### 4 Comparison with experimental studies

The formulation proposed here was implemented in the ABAQUS Finite Element code [54] as a user-written element subroutine (UEL). To verify the
element under different loading conditions, the double cantilever beam (DCB) test, the end notched flexure (ENF) test, and mixed-mode bending (MMB) tests are simulated. The numerical predictions are compared with experimental data. The DCB test consists of pure mode I delamination. The ENF tests measure pure mode II interlaminar fracture toughness, and the MMB delaminate under Mixed mode I and II. In the absence of mode III loading, \( G_{\text{shear}} = G_{II} \). To investigate the accuracy of the formulation in the simulation of delamination DCB, ENF and MMB simulations are conducted for PEEK/APC2, a thermoplastic matrix composite material.

4.1 Mode I, mode II and mixed-mode I and II delamination growth for a PEEK composite

The most widely used specimen for mixed-mode fracture is the mixed-mode bending (MMB) specimen shown in Figure 7, which was proposed by Reeder and Crews [55], [56] and later re-designed to minimize geometric nonlinearities [57]. This test method was recently standardized by the American Society for Testing and Materials [58].

![Fig. 7. MMB test specimen](image)

The main advantages of the MMB test method are the possibility of using virtually the same specimen configuration as for mode I tests, and the capability of obtaining different mixed-mode ratios, ranging from pure mode I to pure mode II, by changing the length \( c \) of the loading lever shown in Figure 7. An 8-node decohesion element is used to simulate DCB, ENF and MMB tests in unidirectional AS4/PEEK carbon-fiber reinforced composite. The specimens simulated are 102-mm-long, 25.4-mm-wide, with two 1.56-mm-thick arms. The material properties are shown in Table 1, and a penalty stiffness \( K = 10^6 \text{N/mm}^3 \) is used.

Models using 150 decohesion elements along the length of the specimens, and 4 decohesion elements along the width, are created to simulate the ENF and MMB test cases. The initial size of the delamination is simulated by placing open decohesion elements along the length corresponding to the initial delamination of each specimen (see Table 2). These elements are capable of dealing with the contact conditions occurring for mode II or mixed-mode I and II loading, therefore avoiding interpenetration of the delamination faces. The model of the DCB test specimen uses 102 decohesion elements along the length of the specimen. The different $G_{II}/G_T$ ratios are simulated by applying different loads at the middle and at the end of the test specimen. The determination of the middle and end loads for each mode ratio is presented in [24]. The experimental results relate the load to the displacement of the point of application of the load $P$ in the lever (load-point displacement, Figure 7). Since the lever is not simulated, it is necessary to determine the load-point displacement from the displacement at the end and at the middle of the specimen, using the procedure described in [24]. The B-K parameter $\eta = 2.284$ is calculated by applying the least-squares fit procedure proposed in [24] to the experimental data shown in Table 2. Figure 8 shows the numerical predictions and the experimental data for all the test cases simulated, and Table 3 shows the comparison between the predicted and experimentally determined maximum loads. It can be concluded that a good agreement between the numerical predictions and the experimental results is obtained. The largest difference ($-8.1\%$) corresponds to the case of an MMB test specimen with $\frac{G_{II}}{G_T} = 20\%$. This fact is not surprising, since the largest difference between the
Numerical and experimental results

Fracture toughness experimentally measured and the one predicted using the B-K criterion occurs for \( G_{II}/G_T = 20\% \) (see [24]).

### 5 Concluding remarks

A thermodynamically consistent damage model for the simulation of progressive delamination based on Damage Mechanics was presented. A constitutive equation for the interface was derived from the variation of the free energy of the interface. The resulting damage model simulates delamination onset and
delamination propagation. The constitutive equation proposed uses a single variable to track the damage at the interface under general loading conditions. A new initiation criterion that evolves from the Benzeggagh-Kenane propagation criterion has been developed to assure that the model accounts for changes in the loading mode in a thermodynamically consistent way and avoids material healing. The damage model was implemented in the finite element code ABAQUS by means of a user-written decohesion element. The material properties required to define the element constitutive equations are the interlaminar fracture toughnesses, the penalty stiffness, and the strengths of the interface. In addition, a material parameter $\eta$, which is determined from standard delamination tests, is required for the Benzeggagh-Kenane mode interaction law.

Three examples were presented that test the accuracy of the method. Simulations of the DCB and ENF tests represent cases of single-mode delamination. MMB tests were simulated at various proportions of mode I and II loading conditions. The examples analyzed are in good agreement with the test results and they indicate that the proposed formulation can predict the strength of composite structures that exhibit progressive delamination. Although the examples presented in this work were obtained for composite specimens containing pre-existing delaminations, the formulations can be extended to composite structures without any pre-existing defects.

APPENDIX A

A Algorithm

In this section the algorithm implementation of the previous model is outlined. The algorithm contemplates two different options for the computation of the initiation and propagation surfaces. The first option uses the expression for the critical energy release rate formulated by Benzeggagh and Kenane [35]. The second option uses a Power-law form for the failure criterion, which is widely used in the literature for the simulation of delamination. The Power-law criterion is given by:

$$
\left( \frac{G_I}{G_{Ic}} \right)^\eta + \left( \frac{G_{II}}{G_{IIc}} \right)^\eta = 1 \quad \text{(A.1)}
$$

Initial data for time $t+1$

Material properties: $G_{IC}, G_{IIC}, G_{IIIc}, E, \eta, \tau^0_{shear}, \tau^0_3$
Current values: $\Delta_3, \Delta_{\text{shear}}, d'$

1) Determine mixed-mode ratios

$$\beta = \frac{\Delta_{\text{shear}}}{\Delta_3 + \Delta_{\text{shear}}} \quad (A.2)$$

$$B = \frac{\beta^2}{1 + 2\beta^2 - 2\beta} \quad (A.3)$$

2) Determine pure mode onset displacements

$$\Delta_0^i = \tau_0^i \frac{K}{i} \quad i = 3, \text{shear} \quad (A.4)$$

3) Determine mixed-mode onset displacement

$$\text{Benzeggagh – Kenane (BK)}$$

$$\Delta_0^i = \left[ \left( \frac{1}{\beta} \right) \Delta_0^i \right] + \left( \frac{1}{\beta} \right) \Delta_{\text{shear}}^i \quad \eta^i \quad (A.5)$$

$$\text{Power law (PL)}$$

$$\Delta_0^i = \frac{\sqrt{1 + 2\beta^2 - 2\beta \Delta_0^i \Delta_{\text{shear}}^i}}{\left[ \left( \frac{1}{\beta} \right) \Delta_0^i \right]^2 + \left( \frac{1}{\beta} \right) \Delta_{\text{shear}}^i \eta^i} \quad (A.5)$$

4) Determine mixed-mode final displacements

$$\text{BK}$$

$$\Delta_f = \frac{2}{K \Delta_0^i} \left[ G_{Ic} + (G_{IIc} - G_{Ic}) \right] \quad [B]^\eta \quad (A.6)$$

$$\text{PL}$$

$$\Delta_f = \frac{2}{K \Delta_0^i} \left[ \left( \frac{1}{\beta} \right)^2 \right] \eta^i + \left( \frac{1}{\beta} \right) \eta^i \quad (A.6)$$

5) Evaluate displacement jump norm

$$\lambda = \sqrt{(\Delta_3)^2 + (\Delta_{\text{shear}})^2} \quad (A.7)$$

6) Update internal variables

$$r^t = \frac{\Delta_0^0 \Delta_f}{\Delta_f - d^f \left[ \Delta_f - \Delta_0^0 \right]} \quad (A.8)$$

$$r^{t+1} = \max \left\{ r^t, \lambda^{t+1} \right\} \quad (A.9)$$

$$d^{t+1} = \frac{\Delta_f (r^{t+1} - \Delta_0^0)}{r^{t+1} (\Delta_f - \Delta_0^0)} \quad (A.10)$$
(7) Compute tangent stiffness tensor

\[ \mathbf{D}^{\text{tan}} = \mathbf{D}^{\text{tan}}_s + \mathbf{D}^{\text{tan}}_k \]  
(A.11)

where

\[ \mathbf{D}^{\text{tan}}_s = \begin{bmatrix} (1 - d) k & 0 & 0 \\ 0 & (1 - d) k & 0 \\ 0 & 0 & (1 - d \frac{\Delta \chi}{\Delta \kappa}) k \end{bmatrix} \]  
(A.12)

and \( \mathbf{D}^{\text{tan}}_k \) depends on the loading/unloading conditions:

\[
\text{IF} \ (\lambda^{t+1} < r^t \text{ or } \Delta^f < \lambda^{t+1}) \]

\[ \mathbf{D}^{\text{tan}}_k = 0 \]  
(A.13)

\[
\text{IF} \ (r^t < \lambda^{t+1} < \Delta^f) \]

\[ \mathbf{D}^{\text{tan}}_k = \begin{bmatrix} -kH \Delta_1 \Delta_1 & -kH \Delta_1 \Delta_2 & -kH \Delta_1 \Delta_3 \left( \frac{\Delta \chi}{\Delta \kappa} \right) \\ -kH \Delta_2 \Delta_1 & -kH \Delta_2 \Delta_2 & -kH \Delta_2 \Delta_3 \left( \frac{\Delta \chi}{\Delta \kappa} \right) \\ -kH \Delta_3 \left( \frac{\Delta \chi}{\Delta \kappa} \right) \Delta_1 -kH \Delta_3 \left( \frac{\Delta \chi}{\Delta \kappa} \right) \Delta_2 -kH \Delta_3 \Delta_3 \left( \frac{\Delta \chi}{\Delta \kappa} \right) \end{bmatrix} 
\]  
(A.14)

where for a bilinear constitutive law \( H \) is given by equation 54.

(8) Compute tractions

\[
\begin{bmatrix} \tau_1 \\ \tau_2 \\ \tau_3 \end{bmatrix} = (1 - d) k \begin{bmatrix} \Delta_1 \\ \Delta_2 \\ \Delta_3 \end{bmatrix} - d k \begin{bmatrix} 0 \\ 0 \\ \langle - \Delta_3 \rangle \end{bmatrix} 
\]  
(A.15)

**Abstract:**
A thermodynamically consistent damage model for the simulation of progressive delamination under variable mode ratio is presented. The model is formulated in the context of the Damage Mechanics (DM). The constitutive equations that result from the variation of the free energy with damage are used to model the initiation and propagation of delamination. A new delamination initiation criterion is developed to assure that the formulation can account for changes in the loading mode in a thermodynamically consistent way. Interfacial penetration of two adjacent layers after complete decohesion is prevented by the formulation of the free energy. The model is implemented into the commercial finite element code ABAQUS by means of a user-written decohesion element. Finally, the numerical predictions given by the model are compared with experimental results.

**Subject Terms:** Progressive delamination; Decohesion elements; Laminated composites; Debonding; Continuum Damage Mechanics
