LONGITUDINAL STABILITY AND STALLING CHARACTERISTICS OF
A 1/8.33-SCALE MODEL OF THE REPUBLIC XF-12 AIRPLANE

By Edward Pepper and Gerald V. Foster

SUMMARY

The XF-12 airplane is a high performance, photo-reconnaissance aircraft designed by the Republic Aviation Corporation for the Army Air Forces. A series of tests of a 1/8.33-scale powered model was conducted in the Langley 19-foot pressure tunnel to obtain information relative to the aerodynamic design of the airplane. This report presents the results of tests to determine the static longitudinal stability and stalling characteristics of the model.

From this investigation it was indicated that the airplane will possess a positive static margin for all probable flight conditions. The stalling characteristics are considered satisfactory in that the stall initiates near the root section and progresses toward the tips. Early root section stalling occurs, with the flaps retracted and may cause undesirable tail buffeting and erratic elevator control in the normal flight range. From considerations of sinking speed landing flap deflections of 40° may be preferable to 55° or 65°.

INTRODUCTION

The XF-12 airplane was designed by the Republic Aviation Corporation to provide a long-range, high-altitude, high-speed, photo-reconnaissance aircraft for the Army Air Forces. The airplane is conventional in design with a normal gross weight of 103,000 pounds, a wing span of 129.17 feet and a wing area of 1640 square feet. The airplane is equipped with four supercharged Pratt & Whitney R-4360 engines, capable of delivering 3000 horsepower at take-off.
During the early design stages of the XF-12 airplane, a preliminary analysis of the longitudinal stability characteristics was made by NACA (reference 1). Subsequent investigations by NACA were made to determine the aerodynamic characteristics of several of the component parts of the XF-12 airplane, the results of which are reported in references 2 to 9.

To furnish additional information pertinent to the aerodynamic characteristics of the XF-12 design, the Air Materiel Command, Army Air Forces, has requested that an investigation be conducted in the Langley 19-foot pressure tunnel of a 1/8.33-scale complete model of the XF-12 airplane. This paper presents the results of that part of the investigation made to determine the static longitudinal stability and stalling characteristics for various power conditions and flap deflections.

COEFFICIENTS AND SYMBOLS

The positive directions of the forces, moments, and angular displacements of the airplane and control surfaces are shown in figure 1. The coefficients and symbols used are as follows:

- **C_L**: Lift coefficient \((L/qS)\)
- **C_X**: Longitudinal-force coefficient \((X/qS)\)
- **C_m**: Pitching-moment coefficient \((M/qSc)\)
- **T_c**: Effective thrust coefficient \((T/2qD^2)\)
- **Q_c**: Torque coefficient \((Q/2qD^3)\)
- **L**: Lift \((-Z)\)
- **X**: Force along longitudinal axis
- **Z**: Force along vertical axis
- **M**: Pitching-moment about center of gravity
- **T**: Effective thrust of one propeller
- **Q**: Torque of one propeller
free-stream dynamic pressure \( \frac{1}{2} \rho V^2 \)

mean aerodynamic chord (M.A.C.) of wing 
\[ (2/S \int_0^{b/2} c^2 \, dy = 1.61 \text{ ft for the model}) \]

airfoil section chord

wing span (15.51 ft for the model)

wing area (23.6 sq ft for the model)

propeller diameter (1.941 ft for the model)

mass density of air

free-stream velocity

velocity at duct inlet

indicated velocity

Reynolds number \( (\rho V V / \mu) \)

Mach number \( (V/a) \)

sonic velocity

coefficient of viscosity

angle of attack of wing root chord line

stabilizer incidence relative to wing root chord line, positive with trailing edge down

elevator deflection with respect to stabilizer chord line, positive with trailing edge down; subscript "trim" denotes elevator deflection when \( C_m = 0 \)

flap deflection with respect to adjacent wing section chord line

propeller blade angle at 0.75 tip radius
\(\Delta C_m / \Delta \alpha_t\) variation of pitching-moment coefficient with stabilizer incidence

\(\Delta C_m / \Delta \delta_e\) variation of pitching-moment coefficient with elevator deflection

Symbols for the several power conditions are presented in table I.

MODEL AND TESTS

Model

The 1/6.33-scale complete model of the XF-12 airplane is shown in figure 2 set up in the test section of the Langley 19-foot pressure tunnel. Principal dimensions and general design features are presented in figure 3 and table II. The model is of steel-reinforced wood construction. The surfaces were sprayed with lacquer and kept smooth by filling irregularities with glazing putty and finishing with fine abrasive paper. The electric, water, and pressure-tube leads were conducted to the model through the rear support strut fairing.

Wing.—The wing embodies the Republic Aircraft Corporation airfoil sections designated as R-4, 34-318-1 at the root and R-4, 40-413-6 at the tip. The pressure distributions over these airfoil sections are approximately the same as those of NACA 65-series sections with similar camber and thickness. (See reference 5.) The ordinates of these sections are presented in table III. The maximum thickness of the root and tip sections are 18 and 13 percent, respectively, at 40 percent chord. The wing tips have a geometric washout angle of 4° formed by a uniform twist from 52.5 percent of the semispan as shown in figure 3. A straight line perpendicular to the axis of symmetry connects all the 50-percent chord locations.

The wing is equipped with double-slotted, partial-span flaps that extend spanwise from the fuselage to approximately 61.5 percent of the semispan. The model flaps may be deflected 20°, 40°, 55°, and 65° from the retracted position as shown in figure 5 and are fixed in position by suitable steel brackets.

Dive-recovery flaps used during the tests were installed on the lower surface of the wing as shown in figure 6 at 15 percent of the wing chord between the fuselage and the outboard nacelles. Details of the dive-recovery flap installation are given in figure 7.
Tail surfaces.— The horizontal tail is attached above the fuselage to the vertical tail. The model elevators differ from the full-scale tail design in that internally sealed balances are not provided. (See fig. 8.) Felt wiper seals are installed to prevent air-flow through the stabilizer-elevator gap. No elevator trim tabs are provided. The elevator was set manually through a range from 15° to -25° and was fixed in the desired position by hinge clamps. The stabilizer incidence is adjustable through a range from 3° to -6.5° to the wing root chord line. The rudder was locked in the neutral position for this investigation.

The complete empennage (horizontal and vertical tail and after portion of the fuselage) is removable and was replaced by a fuselage tail cone for the test runs with the tail removed. (See fig. 9.)

Wing ducts and nacelles.— The model has duct inlets situated at the leading edge of the wing between the inboard and outboard nacelles. It was found, from studies of the original Republic designed ducts in the Langley propeller-research tunnel, that internal flows of this duct limited the critical speeds of the airplane to unsatisfactorily low values. Consequently a new set of duct lips, designated NACA wing duct inlet number 5, were developed (reference 9) to allow larger values of airplane critical speed. Both duct inlets were tested on the model. A comparison of the physical characteristics of the two sets of duct lips is given in figure 10.

The internal air flows were regulated by means of adjustable doors at the exit ports, located on the underside of the nacelles as noted in figure 6. Measurements of the quantity rate of flow through the ducts were obtained with the aid of total- and static-pressure tubes located in the exit ports and connected to a multiple-tube manometer.

Each of the four model nacelles was provided with adjustable cowl exit openings to allow regulation of the internal flow through the cowl. The model nacelle afterbodies are faired to moderately streamlined shapes. The full-scale nacelle installations differ from this in that the afterbodies are cut off blunt to allow an opening for the turbo-supercharger exhaust (to augment the propeller thrust).

Propellers and motors.— The four-blade, right-hand, adjustable-pitch, tractor model propellers are geometrically similar to the airplane propellers. The propeller hubs are externally contoured to simulate the spinners. Dummy spinners were available for tests with propellers removed.
Each of the four propellers was driven by a water-cooled induction motor that was housed within the nacelle and was capable of continuously developing 20 foot-pounds of torque at rotational speeds up to approximately 6000 rpm. A variable frequency alternator supplied the current and speed control for the four motors.

**Fuselage and protuberances.**—The fuselage has a fineness ratio of 9.03:1 and is circular in cross section about a straight line extending from the nose to the tail. The maximum diameter of the fuselage occurs at the 50 percent chord line of the wing root chord or about 38.6 percent of the fuselage length from the nose. The fuselage is equipped with models of an astrodome and a radar dome.

When the flaps were deflected the tricycle landing gear and wheel-well doors were extended to simulate the full-scale airplane configuration. The wheel wells in the fuselage and under surface of the wing were not reproduced on the model.

**Test Conditions and Methods**

The investigation was made with the density of the air in the tunnel maintained at approximately 0.00535 slug per cubic foot. Most of the tests were conducted at a dynamic pressure of approximately 27.5 pounds per square foot which gave a Reynolds number of about 2,100,000 and a Mach number of approximately 0.09. A few test runs were conducted with propellers removed at a dynamic pressure of approximately 55 pounds per square foot, which roughly corresponds to a Reynolds number of 3,400,000 and a Mach number of 0.13.

**Stabilizer and elevator tests.**—Most of the tests were made by varying the angle of attack from low to high values for each of the selected stabilizer and elevator settings. The stabilizer characteristics were obtained for $\alpha = 0^\circ$, $-20^\circ$, and $-6.5^\circ$ with $\delta_e$ equal to $0^\circ$. For the elevator tests the stabilizer incidence was set at $-2^\circ$ and values of $\delta_e$ were chosen to cover a satisfactory range of flight conditions.

**Power conditions.**—The full-scale power conditions simulated during the test are listed in table I. The model propellers were operated so that $T_c$ varied with $C_L$ for the several power conditions as shown in figure 11. The power condition for a gross weight of 77,500 pounds was selected to cover the condition with very light loading and may also be used to some extent to estimate the airplane characteristics with power ratings above 3000 horsepower.
per engine. The values given in figure 10 are based on estimates of the full-scale propeller characteristics with the thrust line incidence equal to 0°. The variation of $T_c$ with $C_L$ for the 100-percent rated-power condition (not shown) and $(M_p)^2$ are approximately the same. No attempt was made to simulate the relatively small amount of thrust due to the reaction of the full-scale turbosupercharger exhaust. Calibrations of the model propeller were made with the thrust line incidence at 0° to determine the variation of $T_c$ with $Q_c$. A blade angle setting of 21.5° was selected to obtain a reasonable approximation of $Q_c$ as shown in figure 12. An analysis indicated that variations from these curves would have small effect on the longitudinal stability results and therefore did not warrant other blade angle settings during the test.

Test runs of the model with power on were made by varying the thrust coefficient with the angle of attack at a constant value of dynamic pressure to simulate constant power conditions. For the military power conditions, the maximum values of lift coefficient that could be attained during the tests were limited by the amount of torque available from the model motors.

Duct and nacelle air-flow conditions.—While most of the investigation of the 1/8.33-scale complete model of the Republic XF-12 airplane was conducted with the NACA wing duct inlet number 5, some preliminary tests were made to determine the effect of the Republic designed wing duct inlets on the stall progression and maximum lift coefficient. As it was infeasible to simulate full-scale air flow for all flight conditions, values of duct entrance velocity ratio were selected that would closely represent the full-scale conditions most generally approached in flight. An attempt was made to simulate these conditions by adjustment of the exit port doors. The values of $V_e/V$ obtained during the test are as follows:

<table>
<thead>
<tr>
<th>$\delta_f$ (deg)</th>
<th>$\alpha$ (deg)</th>
<th>$V_e/V$</th>
</tr>
</thead>

<td>11.6</td>
<td>0.41</td>
<td>0.86</td>
</tr>
</tbody>
</table>

The changes in entrance velocity ratio were roughly proportional to the inlet area change of the two duct configurations so that values of flow coefficient for the two ducts were approximately the same. When the flaps were deflected 20°, 40°, and 55°, the exit-port settings were the same as for the condition with the flaps deflected 65°.

No measurements were made of the quantity rate of air flow through the nacelles. However, high values were sustained by utilizing the maximum openings at the cowl exits in all tests except where noted.

Test runs with tufts attached to the model were made with maximum opening of cowl exit and with cowl entrances sealed as shown in figure 13. These tests indicated that the internal air flows obtained during the investigation should not adversely influence the longitudinal stability results to any appreciable extent.

Tuft studies.— The flow characteristics over the upper surface of the wing, nacelles, and fuselage were determined by the observation of wool tufts. The tufts were fastened to the wing upper surface with thin strips of cellulose tape at approximately 30, 50, 70, and 90 percent of the wing chord and spaced about 5 inches spanwise. The attitude of the model was changed during the test runs from low to high values of angle of attack. At every angle of attack that the flow pattern changed appreciably, as indicated by the tuft behavior, sketches were made and motion picture film records were obtained.

DATA COMPUTATIONS AND CORRECTIONS

The data are referred to the stability axes, which are a system of axes having their origin at the center of gravity in which the Z-axis is in the plane of symmetry and perpendicular to the
relative wind, the X-axis is in the plane of symmetry and perpendicular to the Z-axis and the Y-axis is perpendicular to the plane of symmetry. (See fig. 1.) The pitching moments are computed about the normal center of gravity located on the fuselage center line at 27.43 percent of the mean aerodynamic chord.

Tares caused by model support-strut interference effects were determined from tests of the model with propellers removed. These tares have been applied to the lift, longitudinal-force, and pitching-moment values. Jet-boundary interference corrections have been applied to the longitudinal-force, pitching-moment, and angle-of-attack values. The longitudinal-force and angle-of-attack values have also been corrected for stream angle misalignment.

Test accuracy.—In general, the test accuracy is believed to be as follows:

\[ C_L \pm 0.005 \]
\[ C_X \pm 0.003 \]
\[ C_m \pm 0.004 \]
\[ \alpha, \text{ degrees} \pm 0.05 \]
\[ \delta_c, \text{ degrees} \pm 0.10 \]
\[ \iota_t, \text{ degrees} \pm 0.10 \]

RESULTS AND DISCUSSION

The aerodynamic forces and moments measured during the investigation and analysis of the data are presented in nondimensional coefficient form in figures 14 to 36. All the data are for the model with the NACA wing duct inlet number 5 unless otherwise noted.

STATIC LONGITUDINAL STABILITY

Stabilizer characteristics.—The effects of stabilizer incidence on several aerodynamic characteristics are presented in figures 14 to 17. The results were obtained for several power and flap conditions. Test data of comparable model configurations with the tail removed are also included in these figures. The results indicate that no serious loss of tail effectiveness due
to tail stalling will occur. Increases of power caused increases in the values of $\frac{\partial C_m}{\partial \alpha t}$. The most pronounced changes occur for flaps retracted with values ranging from $-0.042$ for $T_c = 0$ to $-0.072$ for $(M.P.)_1$ at $C_L$ equal $1.40$. For all the flaps deflected conditions tested values of $\frac{\partial C_m}{\partial \alpha t}$ were within the preceding limits. Values of $\frac{\partial C_m}{\partial \alpha t}$ decrease slightly with angle of attack for $T_c = 0$ or propellers removed conditions. It should be noted that sharp breaks in the pitching-moment curves are experienced when the flaps are retracted and the power is moderately high. A possible cause of the breaks may be a decrease in the downwash at the tail resulting from early stalling of the wing-root sections. The wing stalling characteristics are discussed in detail in a subsequent section of this paper.

Elevator characteristics.— Test results are presented in figures 13 to 22 to show the effects of the elevator deflection on several aerodynamic characteristics of the model. The results are for several flap and power conditions. Trends in the variation of $\frac{\partial C_m}{\partial \delta_e}$ are similar to those noted for $\frac{\partial C_m}{\partial \alpha t}$ as expected. The most pronounced changes occur for the flaps retracted condition with values ranging from $-0.029$ for $T_c = 0$, $C_L = 1.20$ to $-0.046$ for $(M.P.)_1$, $C_L = 1.6$. Breaks occur in the pitching-moment curves similar to those experienced with the stabilizer tests as expected. These breaks occur at lift coefficients below the stall and indicate the possibility of encountering erratic elevator control in the high altitude climb condition.

Analysis.— Inasmuch as elevator hinge moments were not measured during the tests, an analysis has been made to estimate only the elevator-fixed static longitudinal stability characteristics of the XF-12 airplane using the results presented in figures 13 to 22. The relation of the center-of-gravity location with the elevator deflection necessary for trim throughout the speed range was estimated for the airplane and is presented in figure 23 for the several flap and power conditions. Also shown on these curves are the corresponding elevator-fixed neutral points determined from figures 14 to 18 by methods explained in reference 10. It is assumed in the derivation of these curves that the elevator effectiveness will not be affected by control-tab deflection and that the effect of the drag component of the airplane on the pitching-moment may be neglected. It is believed that these assumptions are reasonable on the premise that for the range of elevator settings required for trim the control-tab deflection will probably be small so that the variation of tail lift with elevator deflection will not be appreciably affected. Moreover, for all but the low values of $V$, the effect of the drag component of the airplane is negligible and therefore will not
seriously affect the results in the normal speed range. It is believed that the foregoing assumptions are consistent with the accuracy of the test measurements.

In determining $V_1$, a design gross weight of 77,500 pounds was included in the conventional lift equation for level flight to give $V_1 = 135.896 (CL)^{-1/2}$, miles per hour for (M.P.) and 103,000 pounds to give $V_1 = 156.642 (CL)^{-1/2}$, miles per hour for the remaining power conditions. Although these equations are correct for only one speed (level flight), the error involved, is less than 4 percent and corrections are therefore neglected.

It is convenient to use figure 23 to find the elevator deflection necessary for trim for any normal speed and normal center-of-gravity location (25 to 30 percent M.A.C.). It is indicated from these results that sufficient elevator deflection for trim will be available for any flight condition encountered.

For convenience in determining the effects of power on the longitudinal stability, the neutral point results are summarized in figure 24. It may be seen from this figure that, in general, power has a destabilizing effect. The results of the neutral points analysis indicates that a positive static margin will exist for all flight conditions with the gross weight equal to 103,000 pounds when the center of gravity is located at 30 percent mean aerodynamic chord (most rearward location). For flight conditions with (M.P.) the airplane will have a tendency toward instability at speeds below 130 miles per hour.

**LIFT AND STALL CHARACTERISTICS**

NACA wing duct inlet number 5—The effects of flap deflection and increase of Reynolds number on the lift characteristics for the model with the propellers removed are shown in figure 25. Also included are the longitudinal-force and pitching-moment characteristics. An increase of Reynolds number caused an increase in maximum lift and the angle of attack at which maximum lift occurs. At the higher Reynolds numbers the maximum untrimmed lift coefficient with flaps retracted is 1.41; with flaps deflected $55^\circ$ it is 1.98; and with flaps deflected $65^\circ$ it is 2.05.

A rough analysis of the landing flight conditions was made for the airplane with flap deflections of $40^\circ$, $55^\circ$, and $65^\circ$ at 110-percent stalling speed as indicated:
From the preceding values it may be seen that flap deflections of 40° are more favorable from considerations of sinking speed. There is little choice between 55° and 65° for lowest landing speeds. It seems likely that power will be necessary for landing as the sinking speeds for Tc = 0 are considered high. It should be noted that the ground angle for landing can not exceed 9.5°.

An indication of the effects of power on the lift and pitching-moment characteristics may be readily obtained from figure 26 for all the flight conditions tested. It is apparent that increase of power caused marked increases in the value of lift coefficient for all but the low angles of attack and caused decreases in the stable variation of pitching-moment coefficient with lift coefficient.

Lift values measured during the stall studies are shown in figure 27. When the tufts were attached to the wing surface the lift decreased by a slight amount below maximum lift as expected. The effects of the tufts on the stall are believed to be negligible.

The stall progressions for the model with flaps retracted are indicated in figure 28 for Tc = 0 and 0.75 (R.P.). The stall initiated along the trailing edge and gradually spread forward toward the leading edge of the wing as the angle of attack was increased. The stall appeared to be evenly distributed along the wing span so that the tip sections were not stalling out prematurely. The right wing tended to stall more rapidly, especially at the higher power. This phenomenon is associated with the increased angle of attack at the inboard sections of the right wing induced by propeller rotation. This effect indicates that the airplane will probably roll to the right in a stall. Root stalling is desirable at high angles of attack as a means for warning the
pilot through tail buffeting of approaching stall. Early root
stalling, however, may be undesirable because of tail buffeting and
erratic elevator control in the normal flight range.

Figure 29 contains the results of the stall studies of the
model with flaps deflected 65°. Stall progression patterns similar
to those with the flaps retracted are indicated except that less
severe root stalling occurred. Increase of power tended to diminish
the stall at the center sections (behind the wing duct inlet) but
apparently affected the wing spanwise load distribution so that
at high angles of attack the tip stall was more pronounced.

Stall studies were made with the propellers removed at a
Reynolds number of about 3,400,000 as shown in figure 30. The
stall was symmetrically situated over the wing span. The studies
indicate that less tip stalling and more stalling over the center
sections occurred than for the case of the model with propellers
at a Reynolds number of about 2,400,000. These occurrences are not
attributed to the change in test Reynolds number but rather demon-
strate the influence of propeller operation on the stall. It is
believed on the basis of the stall studies that the slipstream from
the propellers, in addition to causing asymmetrical stalls also
tends to clean up the stall between the nacelles by decreasing the
boundary-layer thickness over the wing and hence delaying separation.

With the nacelle cowl entrance sealed the stall results in
figure 31 show little change from those with maximum internal air
flow. (See fig. 30.)

Original wing duct inlet.— The results of preliminary studies
of the aerodynamic characteristics of the model equipped with the
original Republic designed wing duct inlet are presented in
figure 32. A comparison with the lift and pitching-moment character-
istics of the NACA wing duct inlet number 5 (fig. 26) indicates that
the model with the original duct lips has slightly lower values of
maximum lift coefficient. The differences in the pitching-
moment characteristics for the two wing duct inlet arrangements
are small.

The stall progressions for the model with the original wing
ducts are presented in figures 33 and 34. Little difference is
noted between the stalling characteristics of the model equipped
with the NACA wing duct inlet number 5 and of the model with the
original duct inlet.
EFFECT OF DIVE-RECOVERY FLAPs AND LANDING GEAR

Dive-recovery flaps.—The effect of dive-recovery flaps on the aerodynamic characteristics of the model with and without the tail is presented in figure 35. For these tests at comparatively low Mach numbers, the results are consistent with results of tests of other dive-recovery flaps. (See reference 11.) For the condition with the dive-recovery flaps removed, it is believed that model deterioration occurred during the time that elapsed between the runs with the tail on and the tail removed. This would explain to a great extent the apparent discrepancy in the longitudinal-force data where the tail-on condition shows less negative values than the tail-removed condition.

Landing gear.—It is evident from figure 36 that for the condition with propellers removed, extension of the landing gear will not appreciably affect the variation of lift and pitching-moment coefficient with angle of attack; but the longitudinal trim speed will be affected and the lift coefficient values will be decreased by a constant amount. The landing gear also caused a constant increment increase in longitudinal-force coefficient throughout the lift range.

CONCLUSIONS

On the basis of tests of a 1/8.33-scale complete powered model of the Republic XF-12 airplane, the following conclusions are indicated:

1. The airplane will possess a positive static margin for the most rearward center-of-gravity location at 30 percent mean aerodynamic chord except at low speeds at sea level with military power and a low gross weight of 77,500 pounds.

2. Sufficient elevator will be available to trim for all conditions.

3. The stalling characteristics are considered satisfactory for all flight conditions although flap deflection tends to produce less root stalling. However, with flaps retracted early root section stalling occurs and may cause undesirable tail buffeting and erratic elevator control in the normal flight range.
4. Landing flap deflections of 40° may be preferable to 55° or 65° from considerations of sinking speed.

5. The NACA wing duct inlet number 5 will allow slightly larger values of maximum lift coefficient than the Republic designed wing duct inlets.
