Abstract

Aeronautical Telecommunication Network (ATN) has been developed by the International Civil Aviation Organization to integrate Air-Ground and Ground-Ground data communication for aeronautical applications into a single network serving Air Traffic Control and Aeronautical Operational Communications [1]. To carry time critical information required for aeronautical applications, ATN provides different Quality of Services (QoS) to applications. ATN has therefore, been designed as a standalone network which implies building an expensive separate network for ATN. However, the cost of operating ATN can be reduced if it can be run over a public network such as the Internet. Although the current Internet does not provide QoS, the next generation Internet is expected to provide QoS to applications. The objective of this paper is to investigate the possibility of providing QoS to ATN applications when it is run over the next generation Internet. Differentiated Services (DiffServ), one of the protocols proposed for the next generation Internet, will allow network service providers to offer different QoS to customers. Out results show that it is possible to provide QoS to ATN applications when they run over a DiffServ backbone.

1 Introduction

The International Civil Aviation Organization (ICAO) has developed the Aeronautical Telecommunication Network (ATN) as a commercial infrastructure to integrate Air-Ground and Ground-Ground data communication into a single network to serve air traffic control and aeronautical operational communications [1]. One of the objectives of ATN internetwork is to accommodate different Quality of Service (QoS) required by ATSC (Air Traffic Services Communication) and AINSC (Aeronautical Industry Service Communication) applications, and the organizational policies for interconnection and routing specified by each participating organization. In the ATN, priority has the essential role of ensuring that high priority safety related and time critical data are not delayed by low priority non-safety data, especially when the network is overloaded with low priority data.

The time critical information carried by ATN and the QoS required by ATN applications has led to the development of the ATN as an expensive independent network. The largest public network, the Internet, only offers point-to-point best-effort service to the users and hence is not suitable for carrying time critical ATN traffic. However, the rapid commercialization of the Internet has given rise to demands for QoS over the Internet.

QoS is generally implemented by different classes of service contracts for different users. A service class may provide low-delay and low-jitter services for customers who are willing to pay

2The second author is currently with the School of Computer Science, University of Oklahoma, Norman, OK 73072, Tel: (405) 325 8077, email: atiq@ou.edu
a premium price to run high-quality applications, such as, real-time multimedia. Another service class may provide predictable services for customers who are willing to pay for reliability. Finally, the best-effort service provided by current Internet will remain for those customers who need only connectivity.

The Internet Engineering Task Force (IETF) has proposed a few models to meet the demand for QoS. Notable among them are the Integrated Services (IntServ) model [2] and Differentiated Services (DiffServ) [3] model. The IntServ model is characterized by resource reservation; before data is transmitted, applications must set up paths and reserve resources along the path. This gives rise to scalability issues in the core routers of large networks. The DiffServ model is currently being standardized to overcome the above scalability issue, and to accommodate the various service guarantees required for time critical applications. The DiffServ model utilizes six bits in the TOS (Type of Service) field of the IP header to mark a packet for being eligible for a particular forwarding behavior. It does not require significant changes to the existing infrastructure, and does not need too many additional protocols.

A significant cost saving can be achieved if the ATN protocol could be run over the next generation Internet protocol as shown in Figure 1. In this paper, we are interested in developing a framework to run ATN over the next generation Internet. This requires appropriate mapping of parameters at the edge routers between the two networks. The objective of this paper is to investigate the QoS that can be achieved when ATN runs over the DiffServ network in the next generation Internet. Based on the similarity between an IP packet and an ATN packet, our approach is to add a mapping function to the edge DiffServ router so that the traffic flows coming from ATN can be appropriately mapped into the corresponding Behavior Aggregates of DiffServ, and then marked with the appropriate DSCP (Differentiated Service Code Point) for routing in DiffServ domain. We show that, without making any significant changes to the ATN or DiffServ infrastructure and without any additional protocols or signaling, it is possible to provide QoS to ATN applications when ATN runs over a DiffServ network.

The significance of this work is that considerable cost savings could be possible if the next generation Internet backbone can be used to connect ATN subnetworks. The main contributions of this paper can be summarized as follows:

- Propose a framework to run ATN over the DiffServ network.
- Show that QoS can be achieved by end ATN applications when run over the next generation Internet.

The rest of this paper is organized as follows. In Sections 2 and 3, we briefly present the main features of ATN and DiffServ, respectively. In Section 4, we describe our approach for the interconnection of ATN and DiffServ and the simulation configuration to test the effectiveness of our approach. In Section 5, we analyze our simulation results to show that QoS can be provided to end applications in the ATN domain. Concluding remarks are finally given in Section 6.

2 Aeronautical Telecommunication Network (ATN)

In the early 1980s, the International Civil Aviation Organization (ICAO) recognized the increasing limitations of the present air navigation systems and the need for improvements to take civil aviation into the 21st century. The need for changes in the current global air navigation system is due to two principal factors:

- The present and growing air traffic demand which the current system will be unable to cope.
• The need for global consistency in the provisioning of air traffic services during the progression towards a seamless air traffic management system.

The above factors gave rise to the concept of the Aeronautical Telecommunication Network (ATN) [4]. ATN is both a ground-based network providing communications between ground-based users, and an air-ground network providing communications between airborne and ground users. It was always intended that ATN should be built on existing technologies instead of inventing new approaches. The Internet approach was seen as the most suitable approach, and was therefore selected as the basis for the ATN. ATN is made up of End Systems, Intermediate Systems, ground-ground subnetworks and air-ground subnetworks as shown in Figure 1.

2.1 Priority in ATN

The ATN has been designed to provide a high reliability/availability network by ensuring that there is no single point of failure, and by permitting the availability of multiple alternative routes to the same destination with dynamic switching between alternatives. Every ATN user data is given a relative priority on the network in order to ensure that low priority data does not impede the flow of high priority data. The purpose of priority is to signal the relative importance and (or) precedence of data, such that when a decision has to be made as to which data to act first, or when contention for access to shared resources has to be resolved, the decision or outcome can be determined unambiguously and in line with user requirements both within and between applications.

Priority in ATN is signaled separately by the application in the transport layer, network layer, and in ATN subnetworks, which gives rise to Transport Priority, Network Priority and Subnet Priority [5]. Network priority is used to manage the access to network resources. During periods of high network utilization, higher priority NPDUs (Network Protocol Data Units) may therefore be expected to be more likely to reach their destination (i.e. be less likely to be discarded by a congested router), and to have a lower transit delay (i.e. be more likely to be selected for transmission from an outgoing queue) than lower priority packets. In this paper, we focus on network priority which
determines the sharing of limited network resources.

2.2 ATN packet format

Figure 2 shows the correspondence between the fields of an IP packet header and the network layer packet header of ATN. It is seen that the fields of IP and ATN packets carry similar information, and thus can almost be mapped to each other. This provides the possibility for mapping ATN to DiffServ (which uses the IP packet header except for the Type of Service byte) to achieve the required QoS when they are interconnected.

The NPDU header of an ATN packet contains an option part including an 8-bit field named Priority which indicates the relative priority of the NPDU [1]. The values 0000 0001 through 0000 1110 are to be used to indicate the priority in an increasing order. The value 0000 0000 indicates normal priority.

3 Differentiated Services

Differentiated services (DiffServ) is intended to enable the deployment of scalable service discrimination in the Internet without the need for per-flow state and signaling at every hop. The premise of DiffServ networks is that routers in the core network handle packets from different traffic streams by forwarding them using different per-hop behaviors (PHBs). The PHB to be applied is indicated by a DiffServ Codepoint (DSCP) in the IP header of the packet [6]. The advantage of such a mechanism is that several different traffic streams can be aggregated to one of a small number of behavior aggregates (BA) which are each forwarded using the same PHB at the router, thereby simplifying the processing and associated storage [7]. There is no signaling or processing since QoS (Quality of Service) is invoked on a packet-by-packet basis [7].
The Diffserv architecture is composed of a number of functional elements, including a small set of per-hop forwarding behaviors, packet classification functions, and traffic conditioning functions which includes metering, marking, shaping and policing. The functional block diagram of a typical Diffserv router is shown in Figure 3 [7]. This architecture provides Expedited Forwarding (EF) service and Assured Forwarding (AF) service in addition to best-effort (BE) service as described below.

### 3.1 Expedited Forwarding (EF)

This service is also been described as *Premium Service*. The EF service provides a low loss, low latency, low jitter, assured bandwidth, end-to-end service for customers [8]. Loss, latency and jitter are due to the queuing experienced by traffic while transiting the network. Therefore, providing low loss, latency and jitter for some traffic aggregate means there are no queues (or very small queues) for the traffic aggregate. At every transit node, the aggregate of the EF traffic’s maximum arrival rate must be less than its configured minimum departure rate so that there is almost no queuing delay for these premium packets. Packets exceeding the peak rate are shaped by the traffic conditioners to bring the traffic into conformance.

### 3.2 Assured Forwarding

This service provides a reliable services for customers, even in times of network congestion. Classification and policing are first done at the edge routers of the DiffServ network. The assured service traffic is considered *in*-profile if the traffic does not exceed the bit rate allocated for the service; otherwise, the excess packets are considered *out*-of-profile. The *in*-profile packets should be forwarded with high probability. However, the *out*-of-profile packets are not delivered with as high probability as the traffic that is within the profile. Since the network does not reorder packets that belong to the same microflow, all packets, irrespective of whether they are *in*-profile or *out*-of-profile, are put into an *assured queue* to avoid out-of-order delivery.

Assured Forwarding provides the delivery of packets in four independently forwarded AF classes. Each class is allocated with a configurable minimum amount of buffer space and bandwidth. Each
class is in turn divided into different levels of drop precedence. In the case of network congestion, the drop precedence determines the relative importance of the packets within the AF class. Figure 4 [9] shows four different AF classes with three levels of drop precedence.

3.3 Best Effort

This is the default service available in DiffServ, and is also deployed by the current Internet. It does not guarantee any bandwidth to the customers, but can only get the bandwidth available. Packets are queued when buffers are available and dropped when resources are over committed.

4 ATN over Differentiated Services

In this section, we describe in detail the mapping strategy adopted in this paper to connect the ATN and DS domains followed by the simulation configuration we have used to test the mapping.

4.1 Mapping Function

Our goal is to use differentiated services to achieve QoS for ATN to integrate Air/Ground and Ground/Ground data communications into a global Internet serving Air Traffic Control (ATC) and Aeronautical Operations Communications (AOC). The main constraint is that the PHB treatment of packets along the path in the DiffServ domain must approximate the QoS offered in the ATN network. In this paper, we satisfy the above requirement by appropriately mapping the traffic coming from ATN into the corresponding Behavior Aggregates, and then marking the packets with the appropriate DSCP for routing in the DiffServ domain.

To achieve the above goal, we introduce a mapping function at the boundary router between the ATN and DiffServ domain as shown in Figure 5. Packets with different priorities from the ATN domain are first mapped to the corresponding PHBs in the DiffServ domain by appropriately assigning a DSCP according to the mapping function. The packets are then routed in the DiffServ domain where they receive treatment based on their DSCP code. The packets are grouped to BAs in the DiffServ domain. Table 1 shows an example mapping function which has been used in our simulation.

4.2 Simulation Configuration

To test the effectiveness of our proposed mapping strategy between ATN and DiffServ and to determine the QoS that can be provided to ATN applications, we carried out simulation using the ns (Version 2.1b6) simulation tool from Berkeley [10]. The network configuration used in our simulation is shown in Figure 6.

Ten ATN sources were used in our simulation, the number of sources generating high, medium and normal priority packets were two, three and five respectively. Ten ATN sinks served as destinations for the ATN sources.

All the links in Figure 6 are labeled with a (bandwidth, propagation delay) pair. For the purpose of ATN over DiffServ, the mapping function shown in Table 1 has been integrated into the edge DiffServ router. CBR (Constant Bit Rate) traffic was used for all ATN sources in our simulation so that the relationship between the bandwidth utilization and bandwidth allocation can be more easily evaluated.

Inside the DiffServ router, EF queue was configured as a simple Priority Queue with Tail Drop. AF queue was configured as RIO queue and BE queue as a RED [11] queue. The queue weights of EF, AF and BE queues were set to 0.4, 0.4 and 0.2 respectively. Since the bandwidth of the bottleneck link between two DiffServ routers is 5 Mb, the above scheduling weights implies bandwidth allocations of 2 Mb, 2 Mb and 1 Mb for the EF, AF and BE links respectively during periods of congestion at the edge router.

5 Simulation Results

In this section, results obtained from our simulation experiments are presented. The criteria used to evaluate our proposed strategy are described followed by the description of our experiments and numerical results.
5.1 Performance Criteria

To show the effectiveness of our mapping strategy in providing QoS to end ATN applications, we have used goodput, queue size and drop ratio as the performance criteria. In the next section, we present the results of measurements of the above quantities from our simulation experiments.

5.2 Simulation Cases

We use the following four simulation cases to determine the QoS obtained by ATN sources.

- **Case 1: No congestion:** The traffic generated by the each high, medium and normal priority sources were set to 1 Mb, 0.666 Mb and 0.2 Mb respectively. According to the network configuration described in Section 4.2, there are two, three and five sources generating high, medium and normal priority traffic of 2Mb, 2Mb and 1Mb respectively. The amount of traffic of different priority are equal to the corresponding output link bandwidth assigned by scheduler described in Section 4.2. Under this scenario, there should not be any significant congestion at the edge DiffServ router because the sum of the traffic from the sources is equal to the bandwidth of the bottleneck link.

- **Case 2: Normal priority traffic gets into congestion:** The traffic generated by the each high, medium and normal priority sources were set to 1 Mb, 0.666 Mb and 0.6 Mb respectively. According to the network configuration described in Section 4.2, there are two, three and five sources generating high, medium and normal priority traffic of 2Mb, 2Mb and 3Mb respectively. The amount of traffic of high and medium priority are still equal to the corresponding output link bandwidth assigned by scheduler described in Section 4.2. However, the amount of traffic of normal priority is greater than its corresponding output...
link bandwidth. Under this scenario, the normal priority traffic gets into congestion at the edge Diffserv router.

- **Case 3: Medium priority traffic gets into congestion**: The traffic generated by the each high, medium and normal priority sources were set to 1Mb, 1.333 Mb and 0.2 Mb respectively. According to the network configuration described in Section 4.2, there are two, three and five sources generating high, medium and normal priority traffic of 2Mb, 4Mb and 1Mb respectively. The amount of traffic of high and normal priority are still equal to the corresponding output link bandwidth assigned by scheduler described in Section 4.2. However, the amount of traffic of medium priority is greater than its corresponding output link bandwidth. Under this scenario, the medium priority traffic gets into congestion at the edge Diffserv router.

- **Case 4: Both medium and normal priority traffics get into congestion**: The traffic generated by the each high, medium and normal priority sources were set to 1Mb, 1.333 Mb and 0.6 Mb respectively. According to the network configuration described in Section 4.2, there are two, three and five sources generating high, medium and normal priority traffic of 2Mb, 4Mb and 3Mb respectively. The amount of traffic of high priority is still equal to the corresponding output link bandwidth assigned by scheduler described in Section 4.2. However, the amount of traffic of both medium and normal priority are greater than their corresponding output link bandwidth. Under this scenario, both medium and normal priority traffics get into congestion at the edge Diffserv router.

### 5.3 Numerical Results

Table 2 shows the goodput of each ATN source for four different cases described in Section 5.2. Table 3 shows the drop ratio measured at the scheduler for four cases of the three different types of ATN sources. Figures 7, 8, 9 and 10 show the queue size for each of the four case (from Case 1 to Case 4), from which the queuing delay and jitter can be evaluated.

**Case 1** is an ideal case. Each type of source (high, medium and normal priority sources) generates traffic at the rate equal to the bandwidth assigned by the scheduler. Therefore, there is no significant network congestion at the edge Diffserv router. As seen in Table 2, the goodput of each source is almost the same as its traffic generation rate. From Table 3, the drop ratio of each

Figure 7: Queue size plots for Case 1

type of sources is zero. Figure 7 shows the queuing performance of each queue. Because this is an ideal case, the size of each queue is very small. Though the three queues have almost the same average size, we observe that the normal priority queue (mapping to BE queue, according to the mapping function) has the largest jitter. delay).

In case 2, we increased the traffic generation rate of normal priority sources, keeping the rates of the other two types of traffic unchanged. The traffic generating rate of each normal priority source is set to 0.6Mb. In this case, the normal priority traffic gets congested. As shown by Table 3, the drop ratio of normal priority traffic is greatly increased. However, drop ratio for the other two sources still remain at zero. As seen in Table 2, the goodput of normal priority traffic for each source is only about 0.2Mb, instead of the traffic generation rate of 0.6Mb. The reason is that the total available output bandwidth of normal priority traffic has been assigned to 1Mb by scheduler. From Figure 8, we find that the average queue size of the normal priority queue is far greater than the other two types of sources. In addition, the jitter of normal priority traffic is also greater than the other two types of sources. The high priority traffic has the smallest average queue size and the smallest jitter.

Case 3 is very similar to case 2. The only difference is that the medium priority traffic, rather than normal priority traffic, gets into congestion. As expected, we find the drop ratio of medium
priority traffic is increased with other two traffic types remaining at zero, and the goodput is also limited by the output link bandwidth assigned by the scheduler (which is 2Mb). From Figure 9, we find that both the jitter and the average queue size of medium priority traffic are far greater than the other two traffic types. The high priority traffic has the smallest average queue size and the smallest jitter.

In Case 4, we increased the traffic generation rates of both medium and normal priority sources. Both of them get into network congestion in this case. We find from Table 3 that the drop ratio of high priority traffic remains at zero, and drop ratios of both medium priority traffic and normal priority traffic are greatly increased. Furthermore, the drop ratio of normal priority traffic is greater than that of medium priority traffic. As shown by Table 2, the goodput of both the medium and normal priority traffic are limited by their link bandwidths allocated by scheduler. From Figure 10, we see that the normal priority traffic has both the biggest jitter and biggest average queue size. We can also find that the high priority traffic has both the smallest jitter and smallest average queue size.

From the above results, we can arrive at the following observations:

- The high priority traffic always has the smallest jitter, the smallest average queue size and the smallest drop ratio without being affected by the performance of other traffic. In other words, the high priority traffic receives the highest priority, which satisfies the priority requirements of ATN.

- The medium priority traffic has smaller drop ratio, jitter and queue size than the normal priority traffic, even in the presence of network congestion. This also satisfies the priority requirements of ATN.

We therefore, conclude that the priority requirements of ATN can be successfully achieved when ATN traffic is mapped to the DiffServ domain in next generation Internet.

6 Conclusion

In this paper, we have proposed DiffServ as the backbone network to interconnect ATN subnetworks. We have designed a mapping function to map traffic flows coming from ATN with different priorities (indicated by the priority field in ATN packet header) to the corresponding PHBs in the DiffServ domain.

The proposed scheme has been studied in detail using simulation. It has been found that the QoS requirements of ATN can be achieved when ATN runs over DiffServ. We have illustrated our scheme by mapping ATN traffic of three different priorities to the three service classes of DiffServ. The ability of our scheme to provide QoS to end ATN applications has been demonstrated by measuring the drop ratio, goodput and queue size. We found that the high priority ATN traffic has the smallest jitter, the smallest average queue size and the smallest drop ratio, and is unaffected by the performance of other traffic. Moreover, the medium priority ATN traffic has a smaller drop ratio, jitter and queue size than the normal traffic, even in the presence of network congestion.
