How well can we measure the vertical profile of tropospheric aerosol extinction?

Authors:

Submission to: Journal of Geophysical Research - Atmospheres

The recent Department of Energy Atmospheric Radiation Measurement (ARM) Aerosol Intensive Operations Period (AIOP, May 2003) yielded one of the best measurement sets obtained to-date to assess our ability to measure the vertical profile of ambient aerosol extinction $\sigma_\alpha(\lambda)$ in the lower troposphere. During one month, a heavily instrumented aircraft with well characterized aerosol sampling ability carrying well proven and new aerosol instrumentation, devoted most of the 60 available flight hours to flying vertical profiles over the heavily instrumented ARM Southern Great Plains (SGP) Climate Research Facility (CRF). This allowed us to compare vertical extinction profiles obtained from 6 different instruments: airborne Sun photometer (AATS-14), airborne nephelometer/absorption photometer, airborne cavity ring-down system, ground-based Raman lidar and 2 ground-based elastic backscatter lidars. We find the in-situ measured $\sigma_\alpha(\lambda)$ to be lower than the AATS-14 derived values. Bias differences are $0.002 - 0.004$ Km$^{-1}$ equivalent to 12-17% in the visible, or 45% in the near-infrared. On the other hand, we find that with respect to AATS-14, the lidar $\sigma_\alpha(\lambda)$ are higher: Bias differences are $0.004$ Km$^{-1}$ (13%) and $0.007$ Km$^{-1}$ (24%) for the two elastic back-scatter lidars (MPLNET and MPLARM, $\lambda=523$ nm) and $0.029$ Km$^{-1}$ (54%) for the Raman lidar ($\lambda=355$ nm). An unnoticed loss of sensitivity of the Raman lidar had occurred leading up to AIOP and we expect better agreement from the recently restored system.

Looking at the collective results from 6 field campaigns conducted since 1996, airborne in situ measurements of $\sigma_\alpha(\lambda)$ tend to be biased slightly low (17% at visible wavelengths) when compared to airborne Sun photometer $\sigma_\alpha(\lambda)$. On the other hand, $\sigma_\alpha(\lambda)$ values derived from lidars tend to have no or positive biases.

From the bias differences we conclude that the typical systematic error associated with measuring the tropospheric vertical profile of the ambient aerosol extinction with current state of-the-art instrumentation is 15-20% at visible wavelengths and potentially larger in the UV and near-infrared.

Abstract: The recent Department of Energy Atmospheric Radiation Measurement (ARM) Aerosol Intensive Operations Period (AIOP, May 2003) yielded one of the best measurement sets obtained to-date to assess our ability to measure the vertical profile of ambient aerosol extinction $\sigma_{ep}(\lambda)$ in the lower troposphere. During one month, a heavily instrumented aircraft with well characterized aerosol sampling ability carrying well proven and new aerosol instrumentation, devoted most of the 60 available flight hours to flying vertical profiles over the heavily instrumented ARM Southern Great Plains (SGP) Climate Research Facility (CRF). This allowed us to compare vertical extinction profiles obtained from 6 different instruments: airborne Sun photometer (AATS-14), airborne nephelometer/absorption photometer, airborne cavity ring-down system, ground-based Raman lidar and 2 ground-based elastic backscatter lidars. We find the in-situ measured $\sigma_{ep}(\lambda)$ to be lower than the AATS-14 derived values. Bias differences are $0.002 - 0.004$ Km$^{-1}$ equivalent to 12-17% in the visible, or 45% in the near-infrared. On the other hand, we find that with respect to AATS-14, the lidar $\sigma_{ep}(\lambda)$ are higher: Bias differences are $0.004$ Km$^{-1}$ (13%) and $0.007$ Km$^{-1}$ (24%) for the two elastic back-scatter lidars (MPLNET and MPLARM, $\lambda$=523 nm) and $0.029$ Km$^{-1}$ (54%) for the Raman lidar ($\lambda$=355 nm). An unnoticed loss of sensitivity of the Raman lidar had occurred leading up to AIOP and we expect better agreement from the recently restored system.

Looking at the collective results from 6 field campaigns conducted since 1996, airborne in situ measurements of $\sigma_{ep}(\lambda)$ tend to be biased slightly low (17% at visible wavelengths) when compared to airborne Sun photometer $\sigma_{ep}(\lambda)$. On the other hand, $\sigma_{ep}(\lambda)$ values derived from lidars tend to have no or positive biases.

From the bias differences we conclude that the typical systematic error associated with measuring the tropospheric vertical profile of the ambient aerosol extinction with current state-
of-the art instrumentation is 15-20% at visible wavelengths and potentially larger in the UV and near-infrared.

1 Introduction

A major uncertainty in predicting future changes to the Earth system in general, and its climate in particular, stems from the difficulty of modeling the effects of atmospheric aerosols. In fact, recent modeling studies debate to what extent controlling the emission of aerosol (i.e. reducing the emission of light-absorbing aerosol) into the Earth’s atmosphere may be a feasible way to slow global warming [Jacobson, 2002; Hansen et al., 2000; Sato et al., 2003; Penner et al., 2003; Penner, 2003]. The current low confidence in the estimates of aerosol induced perturbations of the Earth’s radiation balance is caused by the highly non-uniform compositional, spatial and temporal distribution of tropospheric aerosols owing to their heterogeneous sources and short lifetimes.

Aerosols affect climate through a variety of pathways. These pathways include direct effects on the scattering and absorption of radiation, indirect effects caused by aerosol roles in cloud microphysics, and “semi-direct” effects caused by aerosol modification of atmospheric heating, temperature profiles, convection, and large-scale horizontal transport [e.g., Ackerman et al., 2000; Chameides and Bergin, 2002; Lelieveld et al., 2002; Menon et al., 2002]. Many of these pathways can affect precipitation, and thus aerosols are intimately linked to the hydrological cycle [e.g., Ramanathan et al., 2001; Rotstyn and Lohmann, 2002].

Monitoring the global distribution of aerosols requires the combination of continuous observations from satellites, networks of ground-based instruments, and dedicated field experiments [Kaufman et al., 2002].
The globally distributed AErosol RObotic NETwork (AERONET) consisting of ~200 Sun- and sky-scanning ground-based automated radiometers provides column measurements of aerosol optical properties, with up to ten years of observations in some locations [Holben et al., 2001]. These data are used extensively for the validation of satellite-derived aerosol properties [e.g. Diner et al., 2001; Torres et al., 2002; Chu et al., 2003]. In situ measurements of aerosol optical properties and composition are made by numerous ground-based networks around the world [e.g. Delene and Ogren, 2002; VanCuren, 2003]. Ground-based lidar networks monitoring the vertical distribution of aerosols are also emerging [Welton et al., 2001, Ansmann et al., 2003]. The era of continuous satellite-based observation of the vertical distribution of tropospheric aerosols has begun very recently with the launch of the Geoscience Laser Altimeter System (GLAS) in January 2003 [Spinhirne et al., 2003].

Here, we assess the accuracy with which the vertical profile of aerosol extinction (a fundamental aerosol property) can currently be measured with state-of-the art instrumentation. We cannot stress enough that for climate considerations it is the properties of the unaltered aerosol at its ambient concentration and thermodynamic state that are of interest. Hence the accuracy assessment presented here applies to the measurement of the vertical profile of ambient aerosol extinction. To arrive at this assessment we rely on comparisons of ambient aerosol extinction profiles obtained in coordinated field campaigns that include in situ and remote sensing measurements of aerosols aboard airborne platforms over surface-based lidars. We start with the results of a recent campaign, the Department of Energy Atmospheric Radiation Measurement (ARM) Aerosol Intensive Operations Period (AIOP, May 2003), and then consider these results in the context of findings from other field campaigns conducted since 1996.
AIOP yielded one of the best-suited measurement sets obtained to-date to assess our ability to measure the vertical profile of ambient aerosol extinction. During one month, a heavily instrumented aircraft with well characterized aerosol sampling ability carrying a combination of well proven and new aerosol instrumentation, devoted most of the 60 available flight hours to flying vertical profiles over the heavily instrumented ARM Southern Great Plains (SGP) Climate Research Facility (CRF) [Ackerman and Stokes, 2003]. This allows us to compare vertical extinction profiles obtained from 6 different instruments: airborne Sun photometer, airborne nephelometer/absorption photometer, airborne cavity ring-down system, ground-based Raman lidar and 2 ground-based elastic backscatter lidars.

2 Measurements

2.1 Airborne Measurements

2.1.1 The Twin Otter aircraft

The Twin Otter is operated by the Marina, California, based Center for Interdisciplinary Remotely-Piloted Aircraft Studies (CIRPAS) [Bluth et al., 1996; Bane et al., 2004]. Between May 6 and May 29, 2003, the Twin Otter performed 16 research flights out of Ponca City, Oklahoma, Airport. All flight patterns were anchored at the ARM SGP CRF (36.60°N, 97.48°E, 319 m), 32 km west of Ponca City. For the AIOP campaign the maximum flight altitude was 5.6 km.

2.1.2 Aerosol Extinction from Sun photometry aboard the Twin Otter

The NASA Ames Airborne Tracking 14-channel Sun photometer (AATS-14) measures the transmission of the direct solar beam in 14 spectral channels (354 to 2139 nm). AATS-14 is an enhanced version of the AATS-6 instrument [Matsumoto et al., 1987].
The AATS-14 tracking head is mounted outside the aircraft skin to minimize blockage by aircraft structures and to avoid data contamination by aircraft-window effects. The instrument locates and tracks the Sun without input from an operator and records data in a self-contained data system. Using aircraft-provided data on latitude, longitude and ambient static pressure, aerosol (or particulate) optical depth $\tau_p(\lambda)$ and columnar water vapor (CWV) are computed and displayed in real-time.

AATS-14 made its first science flights during the Tropospheric Aerosol Radiative Forcing Observational Experiment (TARFOX) in July 1996 [Russell et al., 1999a,b]. Since then, AATS-14 has been operated on many aircraft in numerous aerosol oriented field experiments: ACE-2 [Schmid et al., 2000], SAFARI 2000 [Schmid et al., 2003a], ACE-Asia [Schmid et al., 2003b], CLAMS [Redemann et al., 2005], SOLVE-2 [Livingston et al., 2005; Russell et al., 2004a], and ADAM [Bucholtz et al., 2003].

During AIOP, AATS-14 operated successfully on all 16 Twin Otter research flights. Conditions in the boundary layer tended to be relatively turbulent, resulting in larger (compared to flights over the ocean surface) AATS-14 tracking errors. Measurements exceeding a tracking error of 1° were flagged as questionable data points and not used for this study. The tracking capabilities of AATS-14 under such bumpy conditions have recently been improved by changing settings in the tracking software. To avoid contamination of the AATS-14 entrance window, the tracking head was moved into its park position before flying through clouds.

Our methods for data reduction, calibration, and error analysis have been described previously [Russell et al., 1993a; Schmid and Wehri, 1995; Schmid et al., 1998 and 2001]. A brief summary is given here. The AATS-14 channels are chosen to allow separation of aerosol, water vapor, and ozone transmission. From these slant-path transmissions we retrieve $\tau_p(\lambda)$ in 13
narrow wavelength bands and the columnar amounts of water vapor and ozone. In addition to the corrections for Rayleigh scattering and O$_3$ absorption, some channels require corrections for NO$_2$, H$_2$O and O$_2$-O$_2$ absorption. Cross-sections were computed using LBLRTM 6.01 [Clough, and Iacono, 1995] with the CKD 2.4.1 continuum model using the HITRAN 2000 (v 11.0) line-list [Rothman et al., 2001, 2002] (including an update for water vapor from 04/2001, see http://www.hitran.com/hitran/updates.html). NO$_2$ cross-sections not included in LBLRTM 6.01 were taken from Harder et al. [1997]. NO$_2$ was assumed constant at 2x10$^{-15}$ molecules cm$^{-2}$.

The AIOPT AATS-14 dataset consists of 13 wavelengths (354, 380, 453, 499, 519, 604, 675, 778, 865, 1019, 1241, and 2139 nm) at which we retrieve $\tau_p(\lambda)$ and the 941-nm wavelength, which we use to determine CWV [Schmid et al., 2001].

The columnar O$_3$ content needed to correct for O$_3$ absorption was derived from high altitude (hence low $\tau_p(\lambda)$) spectra (discussed below) by using the spectral fitting technique introduced by King and Byrne [1976] and validated recently by Livingston et al. [2005]. The so-determined columnar O$_3$ content $O_3(z_i)$ corresponds to the flight altitude $z_i$, at which the low $\tau_p(\lambda)$ spectra were measured. Values at all other flight altitudes were determined by scaling a standard O$_3$ profile so it passes through $O_3(z_i)$.

AATS-14 was calibrated at the Mauna Loa Observatory (MLO), Hawaii, 1.5 months before and 1.5 months after the AIOPT campaign using the Langley plot technique [Schmid and Wehrli, 1995]. As a result of band-pass filter degradation, the calibration constants obtained from the post-mission calibration were slightly different from those obtained from the pre-mission calibration. None of the 14 calibration constants had changed by more than 1.6% with 5 channels exhibiting a change of less than 0.5%.
To determine the best calibration constants, $V_0(\lambda)$, applicable to the AIOP data set we inspected spectra with low $\tau_p(\lambda)$ values measured during higher altitude legs. This resulted in 16 spectra taken during 14 flights with $\tau_p(\lambda)$ between 0.01 and 0.06 (at 499 nm) at altitudes 3.1-5.6 km. Starting with calibration constants obtained by linearly interpolating $V_0(\lambda)$ between pre- and post-mission calibration, we then adjusted the calibration constants within the bounds of pre- and post-mission calibration in such a fashion that the retrieved $\tau_p(\lambda)$ yielded “smooth” $\tau_p(\lambda)$ spectra for all 16 high-altitude cases. This procedure revealed that it is best to use slightly different calibration constants for different periods with the AIOP period. This fine-tuning of the calibration constants indicates that some of the optical filters must have degraded in a stepwise fashion.

During AIOP, AATS-14 sampled at 3 Hz with data recorded every 4 seconds consisting of an average of 9 samples taken in the first 3 of the 4 seconds. The sample standard deviation of all science detector outputs is also stored in the data files. These standard deviations were used in our cloud-screening algorithm that is based on clouds exhibiting higher standard deviations than clear sky. This cloud-screening method can be ambiguous when thick and highly variable dust layers are present above the aircraft. However we did not encounter such conditions during AIOP.

Because Sun photometers have a nonzero field of view (FOV), they measure some diffuse light in addition to the direct solar beam. As a result, uncorrected Sun photometer measurements can overestimate direct-beam transmission and hence underestimate $\tau_p(\lambda)$. For most aerosol conditions and Sun photometer FOVs these effects are negligible. For example, Eck et al. [1999] report that for the AERONET sun/sky radiometers, which have FOV half-angle 0.6°, the diffuse-light correction to apparent $\tau_p(\lambda)$ is <0.7% of $\tau_p(\lambda)$, even for desert dust with aerosol effective
radius as large as 1.75 μm. AATS-6 and -14, are designed and built with a relatively large FOV (measured half-angle 1.85°) to help keep the full solar disk in view when sun-tracking during aircraft maneuvers. This larger FOV makes it necessary to assess quantitatively the diffuse light effects on AATS-derived \( \tau_p(\lambda) \) when large particles are dominant. We have previously done this for postvolcanic stratospheric aerosols [Russell et al., 1993a,b] and for the mineral dust dominated Puerto Rico Dust Experiment (PRIDE) [Livingston et al., 2003] and ACE-Asia [Schmid et al. 2003b, Redemann et al., 2003] campaigns. Russell et al. [2004a] established correction factors that correlate well with aerosol effective radius and also with Ångström exponent

\[
\alpha_1(\lambda_1,\lambda_2)=-\ln[\tau_p(\lambda_1)/\tau_p(\lambda_2)]/\ln(\lambda_1/\lambda_2),
\]

We find the correction factors to be negligible for the Ångström exponents encountered during AIOP.

The total uncertainty \( \delta \tau_p(\lambda) \) of the retrieved \( \tau_p(\lambda) \), due to uncertainties in calibration, sun-tracking, signal measurement, airmass computation, and corrections of molecular scattering and absorption, was computed following the procedures given by Russell et al. [1993a] and Schmid et al. [1997]. Note that the impact of tracking errors can be treated as calibration errors taking into account the tracking deviation from the Sun and the measured dependence of each channel’s response on this deviation angle. In most instances, \( \delta \tau_p(\lambda) \) is dominated by the uncertainty in \( V_0(\lambda) \). Neglecting for the moment the dependence of \( \delta \tau_p(\lambda) \) on the other factors mentioned above, one obtains [Russell et al., 1993a]

\[
\delta \tau_p(\lambda) = \frac{1}{m} \frac{\delta V_0(\lambda)}{V_0(\lambda)}
\]
with

\[ m \approx \frac{1}{\cos \theta} \]

Hence a relative uncertainty of 1% in the calibration constant \( V_0 \) will lead to an absolute uncertainty in the aerosol optical depth \( \delta \tau_p(\lambda) \) of 0.01 for a solar zenith angle \( \theta = 0^\circ \) and to smaller uncertainties at larger \( \theta \). The \( \delta \tau_p(\lambda) \) values obtained using all uncertainties mentioned are part of the archived AATS-14 AIOP data. For the data subset and the wavelengths used most prominently in this study, this resulted in average \( \delta \tau_p(\lambda = 453, 519, 675, 1558 \text{ nm}) = 0.003, 0.004, 0.005, 0.003 \). Note that \( \delta \tau_p(\lambda) \) is independent of \( \tau_p(\lambda) \) except for diffuse light errors which we neglect for this study [Russell et al. 1993a].

The uncertainty in CWV was computed following Schmid et al. [1996]. For the subset used here this resulted in average \( \delta \text{CWV} = 0.11 \text{ g/cm}^2 \).

During AIOP the Twin Otter was able to fly as low as 90 m above the land surface, thus allowing measurement of virtually the entire overlying atmospheric column. Flying at different altitudes over a fixed location allows derivation of layer \( \tau_p(\lambda) \) and layer water vapor LWV. Differentiation of \( \tau_p(\lambda) \) or CWV data obtained in vertical profiles allows derivation of spectral aerosol extinction \( \sigma_{e,\rho}(\lambda) \) and water vapor density \( \rho_w \) (see section 3.2).

Because most of the errors in \( \tau_p(\lambda) \) or CWV are of systematic nature, they cancel out when differences (such as layer \( \tau_p(\lambda) \) or LWV) or differentiations (\( \sigma_{e,\rho}(\lambda) \) or \( \rho_w \)) are used. However, since the aircraft requires a finite time to fly a vertical profile which has a finite horizontal component, temporal and horizontal variation of the aerosol above the aircraft will lead to uncertainties in the differentiated quantities. The average horizontal variability during AIOP was
investigated from $\tau_p(\lambda)$ or CWV measurements during 14 low level legs. This average variability, together with the horizontal displacement found during the vertical profiles, was used to estimate the uncertainties in the differentiated quantities following the formulas in Redemann et al. [2003]. This resulted in average $\delta \sigma_p(\lambda = 453, 519, 675, 1558 \text{ nm}) = 0.032, 0.029, 0.024, 0.014 \text{ km}^{-1}$.

2.1.3 Aerosol Extinction from Scattering and Absorption Measurements aboard the Twin Otter

Light-scattering data were obtained from four integrating nephelometers aboard the Twin Otter. One of these was a three wavelength (450, 550, 700 nm) integrating nephelometer (model 3563, TSI St. Paul, MN). The other three were Radiance Research (RR) single wavelength (540 nm) nephelometers (Model RRg03, Radiance Research, Seattle, WA). All four were calibrated against particle-free air and CO$_2$ before and at multiple times during the field deployment and were zeroed with particle-free air before each flight. All of the nephelometers sampled from a shrouded intake whose nominal 50% cutoff diameter was determined to be 8 μm (determined by comparison of cross-calibrated interior and exterior FSSP-100 optical probes [Gao et al., 2003]).

The TSI nephelometer was operated at a flow rate of 30 l/m and with its inlet heater operational at ~35°C. This resulted in the RH inside the instrument being considerably lower than the ambient RH. The RH inside the TSI nephelometer ranged from near 0 to 35% depending on ambient RH.

The hygroscopic behavior of the aerosol was determined from the three RR nephelometers operating at different RH. The three RR nephelometers were operated at RHs below ambient, near 85% and at an intermediate level at a flow rate of 6 l/m. The dependence of light-scattering
on RH, was parameterized by the exponent of equation (4), based on the work of Kasten [1969] (see also Gassó et al., [2000]).

\[
\sigma_{sp}(RH) = \sigma_{sp}(RH_0) \left( \frac{100 - RH}{100 - RH_0} \right)^\gamma
\]

(4)

where the zero subscript refers to some low, reference RH, and the exponent, \( \gamma \), for the measured dependence of light-scattering on RH, is determined by fitting the data to equation (4) as in Gassó et al. [2000].

We then utilized \( \gamma \) to correct the low RH TSI nephelometer scattering signals to the measured ambient RH. Though strictly, the determined \( \gamma \) would apply only to the wavelength of the RR nephelometers (540 nm), we applied it to all 3 TSI nephelometer wavelengths.

Prior to the humidification correction, the TSI nephelometer \( \sigma_{sp}(\lambda) \) values were corrected for angular truncation and non-Lambertian illumination based on the Ångström exponent

\[
\alpha_{sp}(\lambda_1,\lambda_2) = -\ln[\sigma_{sp}(\lambda_1)/\sigma_{sp}(\lambda_2)]/\ln(\lambda_1/\lambda_2).
\]

(5)

as suggested by Anderson and Ogren [1998]. No equivalent correction was done for the RR nephelometers because their truncation parameters have not been determined. However, since the humidograph data are used in a relative sense and dominated by submicrometric particles this is not a large error.

Aerosol light absorption \( \sigma_{ap}(\lambda) \) was measured using an improved version of the 3-wavelength filter-based absorption photometer (\( \lambda = 467, 530, 660 \) nm) described by Virkkula et al. [2005]. The data reduction and correction scheme of Bond et al. [1999] was applied. Because \( \sigma_{ap}(\lambda) \) was measured just downstream of the TSI nephelometer, it was measured under sub-ambient RH (i.e. the same RH as inside the TSI nephelometer to minimize RH dependent
artifacts due to the filter substrate). However, following Hegg et al. [1997], no correction was made for the higher RH of the ambient air since experimental data for such a correction are lacking. A study modeling sulfates with black carbon cores by Redemann et al. [2001] suggests that absorption humidification factors are negligible for a wide range of atmospheric conditions. However, this may not apply to the considerably more complex real-world aerosol.

The resulting $\sigma_{ap}(\lambda)$ and the nephelometer $\sigma_{sp}(\lambda)$ were adjusted from temperature $T_i$ and pressure $p_i$ inside the instruments to ambient (outside the aircraft) $T_{amb}$ and $p_{amb}$ by multiplying them with the factor

$$k = \frac{p_{amb}}{p_i} \frac{T_i}{T_{amb}}$$

(6)

Because the cabin of the Twin Otter is not pressurized, $p_i$ is only slightly higher than $p_{amb}$, however $T_i$ is always larger than $T_{amb}$.

The reported nephelometer $\sigma_{sp}(\lambda)$ values were adjusted from their blue, green and red center wavelengths (450, 550, 700 nm) to those of the PSAP instrument (467, 530, 660 nm) using the Ångström relationship in Eq. (5). For the comparisons shown in this study, the PSAP $\sigma_{ap}(\lambda)$ and nephelometer $\sigma_{sp}(\lambda)$ were adjusted separately (again using an Ångström relationship) to 453, 519 and 675 nm to match AATS-14 and Cadenza (see next section) wavelengths. Aerosol extinction was then calculated as

$$\sigma_{ep}(\lambda) = \sigma_{sp}(\lambda) + \sigma_{ap}(\lambda)$$

(7)

2.1.4 Aerosol Extinction from Cavity-Ring-Down Measurements aboard the Twin Otter

First demonstrated by O'Keefe and Deacon [1988], the cavity ring-down (CRD) technique has been used primarily for gaseous absorption spectroscopy (see various papers in Busch and
Busch [1999]). The use of CRD to measure aerosol extinction is relatively new [Smith and Atkinson, 2001, Strawa et al. 2003]. The principle behind CRD can be best described using the so-called ‘ping-pong’ model. A pulse of laser light is injected into a cavity that consists of two highly reflective mirrors. The mirror reflectivity is typically better than 99.96%. The laser pulse bounces between the two mirrors inside the ring-down cavity like a ping-pong ball. Each time the pulse interacts with the back mirror, a small amount of light (e.g., 0.04%) leaks out. This light is collected and detected with a photomultiplier or similar detector. The intensity of the light leaking out of the back of the ring-down cavity decreases exponentially. It can be shown that the exponential decay, or ring-down time, is related to the mirror reflectivity and the extinction of the material inside the cavity. The extinction coefficient is then obtained by the difference between measurements made when the cell contains filtered air and when the cell contains a particulate-laden flow:

\[
\sigma_a = \frac{1}{c} \left( \frac{1}{\kappa_p} - \frac{1}{\kappa_o} \right)
\]

(8)

where \(c\) is the speed of light, and \(\kappa_p\) and \(\kappa_o\) are the ring-down times of the aerosol laden flow and filtered air, respectively.

Cadenza is the first airborne CRD instrument able to measure aerosol optical properties. The prototype Cadenza instrument as described by Strawa et al. [2003] participated successfully in the Reno Aerosol Optics Study (RAOS) [Sheridan et al., 2005]. Cadenza then flew its first and second successful airborne missions in the ADAM and AIOP experiments aboard the CIRPAS Twin Otter. Detailed descriptions of the instrument, the data analysis and comparisons with other methods during AIOP are reported by Strawa et al. [this issue].
Using the same aerosol inlet as the nephelometers, Cadenza operated successfully on all 16 AIOP science flights continuously measuring $\sigma_{ep}$ at $\lambda=675$ and 1550 nm. Cadenza also measures the aerosol scattering coefficient $\sigma_{sp}$ at $\lambda=675$ nm. The scattering measurements are discussed by Strawa et al. [this issue]. For one minute out of every six minutes Cadenza sampled filtered air. The so-derived $\kappa_0$ values were then linearly interpolated to the times when particle-laden air was sampled and $\sigma_{ep}(\lambda)$ is determined according to Eq. (8). While not deliberately heated, the sample air inside Cadenza was nearly at the temperature of the aircraft cabin and consequently drier than the ambient air. Part of this was caused by ram heating at the aerosol inlet and part was due to heating of the sample line as it carried aerosol from the inlet to the instrument. We then utilized $\gamma$ along with Eq. (4) to correct the low-RH Cadenza $\sigma_{ep}(\lambda)$ to outside-the-aircraft RH and also applied the factor in Eq. (6) to correct to outside-the-aircraft pressure and temperature. Though, strictly, the $\gamma$ was determined from scattering measurements with the RR nephelometers ($\lambda=550$ nm), we applied it to the Cadenza measurements at $\lambda=675$ nm ($\sigma_{ep}$ and scattering portion of $\sigma_{ep}$) and to $\sigma_{ep}(1550$ nm).

2.1.5 Routine Small Aircraft in situ Measurements

Since March 2000, ARM has been measuring in situ aerosol profiles (IAP) by performing routine flights (2-3 times per week) with a small aircraft (Cessna C-172N) over the SGP site. The aerosol instrument package consists of a 3-wavelength TSI nephelometer and a PSAP both measuring at low RH. There is a 1-$\mu$m impactor upstream of the aerosol instruments corresponding to a geometric size cut of approximately 0.79 $\mu$m (for a particle density of 1.6 g/cm$^3$). Although the IAP project was not designed to measure ambient $\sigma_{ep}(\lambda)$, Andrews et al. [2004] have applied (altitude-independent) corrections for low RH, impactor loss, and limited
aircraft ceiling (using information from ground-based nephelometers and Raman lidar) to compare the column-integrated IAP $\sigma_{pe}(\lambda)$ to the $\tau_p(\lambda)$ measured by ground-based Sun photometers. They find the IAP $\tau_p(550 \text{ nm})$ to have a consistent offset of -0.04.

During AIOP the Cessna flew 14 of its standard flights (i.e. level legs at 9 altitudes between 467 and 3660 m). During five of these flights, the Twin Otter trailed the Cessna on its standard legs. This allowed for detailed inter-aircraft comparisons which are presented in companion papers by Hallar et al. [this issue] and Andrews et al. [this issue].

2.2 Ground-Based Measurements

2.2.1 Sun photometers

Three ground-based Sun photometers were used to validate AATS-14 $\tau_p(\lambda)$ during low altitude flybys and to constrain elastic backscatter lidar retrievals. Two of the Sun photometers were AERONET Sun and sky-scanning instruments [Holben et al., 1998, 2001; Eck et al., 1999]. One of the AERONET instruments (#98) is a standard Cimel CE-318 instrument (providing $\tau_p(\lambda)$ at $\lambda=340, 380, 440, 500, 670, 870$ and 1020 nm) that is operated continuously at the SGP CRF. Its data are cloud-screened and quality controlled according to Smirnov et al. [2000]. The other AERONET instrument (#125), an extended-wavelength prototype version with an additional channel at $\lambda=1640$ nm, was deployed specifically for the AIOP. An updated processing scheme was applied to the data from AERONET instrument #125 [Smirnov, 2004].

The third Sun photometer was a Normal Incidence Multi-Filter Radiometer (NIMFR). The instrument consists of a Multi-Filter Rotating Shadowband Radiometer (MFRSR, Harrison et al., [1994]) “head” to which a collimating tube (FOV 5°) is attached. The NIMFR is mounted on a solar tracker. $\tau_p(\lambda)$ at five wavelengths ($\lambda = 415, 500, 615, 673$ and 870 nm) are reported every
20 sec. The data set is cloud screened rigorously based on the stability of $\tau_p(\lambda)$ over about a 10-min period using stability limits that were scaled according to the magnitude of $\tau_p(\lambda)$.

### 2.2.2 Micropulse Lidars

The Micro-Pulse Lidar (MPL) [Spinhirne et al., 1995; Campbell et al., 2002] is a single channel ($\lambda = 523$ nm), autonomous, eye-safe lidar system originally developed at the NASA Goddard Space Flight Center and now commercially available. One of the MPLs (hereafter referred to as MPLARM) is permanently deployed at the ARM SGP CRF. The second MPL was deployed in support of AIOP as part of the NASA Micro-Pulse Lidar Network (MPLNET) [Welton et al., 2001], a network of ground-based MPL systems co-located with AERONET sun/sky radiometers.

Vertical profiles of extinction and backscatter were retrieved independently from both co-located MPL systems. The retrieval of independent extinction and backscatter profiles from single-wavelength elastic backscatter lidar (such as an MPL) faces an inherently ill-posed problem, in that it requires the extraction of two unknowns (extinction and $180^\circ$-backscatter coefficients) from one measurement (the attenuated $180^\circ$-backscatter signal) [Ansmann et al., 1990; Ackermann, 1998]. However, by assuming a constant value of the extinction-to-backscatter ratio ($S_p$) throughout an aerosol layer, and by constraining the integrated extinction profile against an independently determined layer $\tau_p(\lambda)$, it is possible to retrieve a unique solution for the extinction and backscatter profiles and calculate a layer-averaged value for $S_p$ [Welton et al., 2000]. This technique yields reasonable results when the atmosphere is well mixed, but may produce over- or underestimates of extinction at a given altitude when aerosol properties are highly stratified [Welton et al., 2002].
The retrievals of MPLARM and MPLNET assume an altitude-independent extinction-to-backscatter ratio, $S_p$. For the total column aerosol optical depth, the MPLARM processing uses cloud-screened $\tau_p(\lambda)$ retrieved from the NIMFR (discussed above), while MPLNET processing uses similarly screened $\tau_p(\lambda)$ [see Smirnov et al., 2000] from the AERONET Sun/sky radiometer located at the ARM SGP CRF (also described above). In as much as the MPL systems, their calibration and constraining $\tau_p(\lambda)$ were completely independent, the retrievals from MPLARM and MPLNET represent independent determinations using fundamentally similar retrieval techniques.

2.2.3 Raman Lidar

The CRF Raman lidar (CARL) measures backscattered light at the laser wavelength of 355 nm as well as the water vapor and nitrogen Raman shifted returns, at 408 and 387 nm, respectively. $\sigma_{ep}(355\text{nm})$ profiles are computed from the derivative of the logarithm of the Raman nitrogen signal with respect to range [Ansmann et al., 1990]. Unlike with elastic backscatter lidars, the Raman technique allows the derivation of $\sigma_{ep}$ profiles without making an assumption about the profile of the lidar ratio, $S_p$, and without using the total column $\tau_p$ as a constraint [Ansmann et al., 1990; Ferrare et al., 2001].

In April 1997, CARL started to operate at the SGP site as a turnkey, automated system for unattended, around-the-clock profiling of water vapor and aerosols. To facilitate data processing, algorithms were developed to run autonomously delivering water vapor mixing ratio, RH, aerosol scattering ratio, aerosol backscatter coefficient, $\sigma_{ep}$, and linear depolarization ratio, as well as integrated values CWV and $\tau_p$ [Turner et al., 2001, 2002]. The water vapor measurement performance of CARL has been characterized extensively (see references in Ferrare et al. [this issue]). However, initial comparisons of $\tau_p$ and $\sigma_{ep}$ have revealed discrepancies among the
routine CARL, Sun photometer, and the routine small aircraft in situ measurements described above [Ferrare et al., 2003]. AIOP was conducted in part to resolve these discrepancies. Unfortunately, a gradual loss of the sensitivity of CARL starting about the end of 2001 went unnoticed until after AIOP. In an attempt to reduce or remove these adverse impacts, the automated algorithms were modified and the AIOP data were reprocessed. Major modifications that were made to CARL in 2004 (after AIOP) have dramatically improved the system's sensitivity. This is discussed in more detail by Ferrare et al. [this issue].

3 Results

In what follows, we will use the AATS-14 measurement of $\tau_p(\lambda)$ and $\sigma_{ep}(\lambda)$ as a reference against which we will compare all other methods. This choice is driven by the fact that AATS-14 has the largest spectral coverage and can match most of the other instruments' wavelengths relatively closely.

3.1 Comparing $\tau_p(\lambda)$ Obtained from AATS-14 and Ground-based Sun photometers

As done in previous airborne campaigns, we assess the in-flight performance of AATS-14 by comparing against surface based Sun photometers. During most of the flights the Twin Otter flew at least one low-altitude leg (~90 m above ground) near the SGP CRF. We compared the AATS-14 $\tau_p(\lambda)$ with those from the AERONET and NIMFR instruments. During 18 such low-altitude fly-bys the AATS-14 data indicate that the direct beam was not obstructed by clouds. In two cases involving instrument #125, and three cases involving instrument #98, the corresponding AERONET observations had been screened out in the level 2.0 data. For these cases we reverted to the non-cloud screened level 1.0 data. It appears that the NIMFR cloud screening is even more conservative, in that only 12 fly-bys had concurrent NIMFR data. The results of the $\tau_p(\lambda)$ comparison are shown in Table 1.
The level of agreement between AATS-14 and the AERONET instruments is similar to what we found from low altitude fly-bys over AERONET sites in previous campaigns (i.e. PRIDE [Livingston et al., 2003], SAFARI 2000 [Schmid et al., 2003a], and CLAMS [Redemann et al., 2005]. The agreement between AATS-14 and NIMFR found in AIOP is particularly good, in fact operating four Sun photometers (including AATS-6) side-by-side on the ground in previous ARM IOPs did not result in a higher level of agreement [Schmid et al., 1999].

3.2 AATS-14 Vertical Profiles

During AIOP, AATS-14 measured numerous vertical profiles of \( \tau_p(\lambda) \) and CWV. After discarding profiles influenced by considerable spatial inhomogeneity or overlying clouds, we derived spectral aerosol extinction \( \sigma_{\tau_p}(\lambda) \) for 26 profiles by differentiating the \( \tau_p(\lambda) \) profiles. CWV can be determined despite thin overlying clouds, resulting in 35 CWV and water vapor density \( (\rho_w) \) profiles in AIOP. With very few exceptions, the profiles were located directly above the SGP CRF. Figure 1 shows 25 \( \tau_p(\lambda) \) vertical profiles. Figure 2 shows the corresponding \( \sigma_{\tau_p}(\lambda) \) profiles. The profiles of CWV for the same 25 cases and the corresponding \( \rho_w \) profiles are depicted in Figure 3 and Figure 4. To facilitate comparisons, we plotted all profiles on the same scale. Gaps in the \( \tau_p(\lambda) \) or CWV vertical profiles are caused by temporary blockage of the direct solar beam by aircraft structures (tail, antennas) or clouds.

Most vertical profiles were acquired within 20 minutes of flight time. Occasionally, \( \tau_p(\lambda) \) or CWV decreased (increased) when the plane descended (ascended). In a horizontally homogeneous, time-invariant atmosphere, this would be impossible. However, in the real atmosphere it can occur because (1) the Sun photometer can only measure the transmittance of the Sun photometer-to-sun path, (2) that path in general passes through a horizontally inhomogeneous, time-varying atmosphere, and (3) the path and the atmosphere move with
respect to each other as the aircraft moves and the wind blows. Before the Sun photometer $\tau_p(\lambda)$ or the CWV profile is vertically differentiated to obtain $\sigma_{ep}(\lambda)$ or $\rho_w$, it has to be smoothed (in a non-biased manner) to eliminate increases in $\tau_p(\lambda)$ or CWV with height. In this study we first averaged the $\tau_p(\lambda)$ or CWV values over 20-m altitude bins and then used smoothed spline fits for this purpose. However, to avoid over-smoothing at altitudes that exhibit actual variations of $\tau_p(\lambda)$ or CWV we occasionally allow $\sigma_{ep}(\lambda)$ or $\rho_w$ to become slightly negative. This can be seen, for example, in Figure 2 (top row, 2nd panel) and Figure 4 (bottom row, 4th panel).

Some of the profiles in Figure 2 show elevated aerosol layers with $\sigma_{ep}(\lambda)$ values exceeding those in the boundary layer. On May 9, 2003, the aerosol in the elevated layers originated from fires in Mexico [Wang et al., 2004]. The elevated layers observed from May 25 – May 28, 2003 can be traced back to Siberian fires [Colarco et al., this issue]. The smoke from the intense 2003 Siberian biomass burning season ultimately traveled around the globe [Damoah et al., 2004].

3.3 Comparison of Water Vapor Profiles

An aircraft in situ-measurement of $\rho_w$ is more straightforward than measuring ambient $\sigma_{ep}(\lambda)$. Several redundant sensors aboard the Twin Otter measured static temperature $T$, static pressure $p$, and dewpoint temperature $T_d$, from which we computed $\rho_w$ using an expression given by Bögel [1977].

Since the same vertical differentiation procedure is used to derive $\sigma_{ep}(\lambda)$ and $\rho_w$ from the columnar data $\tau_p(\lambda)$ and CWV, comparing $\rho_w$ obtained from AATS-14 and the aircraft in situ sensors should allow conclusions on the robustness of the AATS-14 differentiated profiles of $\rho_w$ and $\sigma_{ep}(\lambda)$. 

21
In Figure 4, we compare 25 (of 35) vertical profiles of $\rho_w$ derived from AATS-14 and an EdgeTech 137-C3 chilled mirror sensor. We observe excellent correspondence between the two measurements. This also demonstrates that the differentiated column method can successfully reproduce thin (~500 m) dry or humid layers. Figure 5 shows a scatter plot containing all data pairs from all 35 profiles. Figure 6 shows a comparison of the layer water vapor (LWV) amounts. LWV is obtained by integrating the in situ measured $\rho_w$ over the vertical span of the profile and for AATS-14 by subtracting the CWV measured at the top of the profile from CWV measured at the bottom. The complete statistics of the comparison are shown in Table 2. The agreement in this study is better than what we found during ACE-Asia [Schmid et al., 2003b] using the same instrumentation (i.e. in ACE-Asia the rms difference in $\rho_w$ and LWV was 25% and 17% vs. 20% and 7% in AIOP). We attribute this to the fact that the AATS-14 AIOP data were acquired using a different brand 941-nm filter which was delivered with potentially more accurate spectral band-pass information.

This study finds the Twin Otter chilled mirror $\rho_w$ to be biased slightly high (5%) with respect to AATS-14. More extensive AIOP water vapor comparisons are discussed in the companion paper by Ferrare et al. [this issue].

3.4 Comparison of Aerosol Extinction Profiles

For the extinction comparison, the profiles from the six methods were binned in 20-m altitude bins between 0 and 8 km above sea level. Naturally, empty bins were excluded from the comparisons. In virtually all of the comparisons the AATS-14 values were used as the independent variable $x$, however the linear regressions were established using the linear least squares bi-sector (lsq-bs) method which minimizes the quadratic distances to the regression line in $x$ and $y$ directions [Sprent and Dolby, 1980].
The Nephelometer+PSAP extinctions were adjusted to the closest AATS-14 wavelengths. In contrast, the CARL, MPL and Cadenza instruments' wavelengths are matched closely enough by an AATS-14 wavelength that no further adjustment is required. This resulted in eight comparisons between AATS-14 and the other five methods at five different wavelengths (see Table 3).

Plotting the profiles allows a visual evaluation on a profile-by-profile basis. Figure 7 makes such a comparison for $\sigma_{ep}(675\text{nm})$ from AATS-14 and Nephelometer+PSAP. In this representation, the Cadenza $\sigma_{ep}(675\text{nm})$ profiles are virtually indistinguishable from Nephelometer+PSAP data points and are therefore not plotted in Figure 7. The high correlation ($r^2=0.963$) between the two in situ measurements is evident in the scatter plot representation in Figure 8. Averaged over all profiles, the Cadenza $\sigma_{ep}(675\text{nm})$ are higher by 4.7% (based on lsq-bs regression line slope) or 6.6% (based on bias) than the Nephelometer+PSAP values. Strawa et al. [this issue] extend the comparison to all 8-sec averages measured during AIOP (not only the 26 altitude-binned profiles studied here) and find the Cadenza $\sigma_{ep}(675\text{nm})$ to be higher by only 0.8% (based on slope of standard regression line forced through origin). This result is obviously a very successful demonstration of the airborne application of the CRD method to measure $\sigma_{ep}(\lambda)$.

Figure 7 shows cases where AATS-14 $\sigma_{ep}(675\text{nm})$ are in good agreement with the in situ measurements, cases where the AATS-14 values oscillate around the in situ data and cases where the AATS-14 values are higher. As an illustration, the scatter plot in Figure 9 shows that Cadenza $\sigma_{ep}(675\text{nm})$ are 10% (based on lsq-bs slope) to 13% (bias) lower than the AATS-14 values.
An alternative way of assessing potential biases in extinction profiles lies in comparing layer \( \tau_p(\lambda) \). Layer \( \tau_p(\lambda) \) is obtained by integrating the in situ or lidar measured \( \sigma_{sp}(\lambda) \) over the vertical span of the profile and for AATS-14 by subtracting the \( \tau_p(\lambda) \) measured at the top from the \( \tau_p(\lambda) \) measured at the bottom of the profile. As an example, the scatter plot in Figure 10 shows that Cadenza layer \( \tau_p(675 \text{ nm}) \) are lower by 15% (based on lsq-bs slope) to 16% (bias) than the AATS-14 values. The layer \( \tau_p(\lambda) \) comparisons from all methods are summarized in Table 4.

The comparisons in Table 3 and Table 4 show that the in situ methods yield consistently lower \( \sigma_{sp}(\lambda) \) and layer \( \tau_p(\lambda) \) than AATS-14. All regression lines exhibit slopes smaller than 1 with very small intercepts indicating a proportional difference rather than a systematic offset. Based on the slopes, we find the Nephelometer+PSAP \( \sigma_{sp}(\lambda) \) to be lower by 7%, 10% and 14% \( (\lambda = 453, 519, 675 \text{ nm}) \). The Cadenza \( \sigma_{sp}(\lambda) \) are lower by 10% \( (\lambda=675 \text{ nm}) \) and 39% \( (\lambda=1550 \text{ nm}) \). These slopes, the slopes in the layer AOD comparison and also the relative biases in \( \sigma_{sp}(\lambda) \) and layer \( \tau_p(\lambda) \) show a distinct wavelength dependence: The low bias of the in situ measurement with respect to AATS-14 increases with increasing wavelength. Partial loss of larger particles during sampling would cause the observed spectral behavior. However, so far we have not considered a potential wavelength dependence of the humidification correction in Eq. (4).

Indeed, a 1-year analysis (March 2000 - February 2001) of surface-based dry and humidified \( \sigma_{sp}(\lambda = 450, 550, 700 \text{ nm} ) \) (submicron particles only) measured with a TSI nephelometer at the SGP CRF [Sheridan et al., 2001], shows a distinct wavelength dependence [Sivaraman et al., 2004]. As illustrated in Figure 11, this suggests that the humidification correction we applied to \( \sigma_{sp}(\lambda) \) might be an overcorrection in the blue and an under correction in the green (and potentially in the near infrared). Kotchenruther et al. [1999] determined a similar wavelength dependence of the humidification factor from airborne measurements during TARFOX. Hence,
part of the spectral behavior of the low bias observed in this study could stem from a not entirely adequate humidification correction.

Lidar data concurrent with a Twin Otter vertical profile were available in 11 (CARL), 13 (MPLNET) and 19 (MPLARM) cases. Comparison of CARL data with AATS-14 and in situ data is discussed in detail in a companion paper [Ferrare et al., this issue]. As summarized in Table 3 and Table 4, CARL $\sigma_{ep}(355 \text{ nm})$ and layer $\tau_p(355 \text{ nm})$ are significantly higher than the AATS-14 values. The lsq-bs regression line between AATS-14 and CARL $\sigma_{ep}(355 \text{ nm})$ reveals an intercept of 0.024 Km$^{-1}$ indicating a systematic offset. The mean difference between the two data sets is 0.029 Km$^{-1}$ or 54% for the average $\sigma_{ep}(354 \text{ nm})$ of 0.053 Km$^{-1}$. We believe that this high bias was primarily due to the unnoticed loss of sensitivity of CARL leading up to AIOP; this reduction in sensitivity led to increased calibration errors, larger random errors, and greater uncertainties in maintaining proper alignment, all of which contributed to these differences. We expect better agreement in future comparisons from the recently upgraded CARL system.

Figure 12 shows vertical profiles of $\sigma_{ep}$ from Nephelometer+PSAP and the two Micro Pulse Lidars. The three data sets show good agreement for the vertical distribution of aerosol layers including fairly thin layers. However, the absolute magnitudes of $\sigma_{ep}(519/523 \text{ nm})$ differ. As shown by Table 3, the lsq-bs regression lines of $\sigma_{ep}(523 \text{ nm})$ of MPLNET vs. AATS-14 and MPLARM vs. AATS-14 reveal intercepts of 0.005 and 0.011 Km$^{-1}$ revealing systematic high biases. The bias difference is 0.004 Km$^{-1}$ (13%) between AATS-14 and MPLNET and 0.007 Km$^{-1}$ (24%) between AATS-14 and MPLARM for the average $\sigma_{ep}(519 \text{ nm})$ of 0.030 Km$^{-1}$. Surprisingly, the layer $\tau_p(519/523 \text{ nm})$ comparisons (Table 4) show high biases with respect to AATS-14 of 0.023 (MPLNET) and 0.025 (MPLARM) that exceed the biases between AATS-14 and AERONET#98 (0.008) and NIMFR (0.006) to which the MPL retrievals are anchored.
Figure 13 shows the cumulative integrals (top-to-bottom) of the MPL $\sigma_{ep}(523 \text{ nm})$ which is equivalent to a $\tau_p$ profile as measured by AATS-14. We find that the cumulative integral of MPLNET and MPLARM $\sigma_{ep}(523 \text{ nm})$ at the top of the AATS-14 profile average 0.014 lower than the AATS-14 $\tau_p(519 \text{ nm})$. This discrepancy is likely caused by the fact that the MPL retrievals determine a maximum layer height $z_{max}$ (typically below 8-10 km) above which $\sigma_{ep}(523 \text{ nm})$ is set to 0. The retrievals then assume that the integrated extinction between the surface and $z_{max}$ make up the total column $\tau_p(523 \text{ nm})$ to which they are anchored. Neglecting the cumulative $\sigma_{ep}(523 \text{ nm})$ from top-of-the-atmosphere to $z_{max}$ will therefore introduce a slight high bias in the MPLNET $\sigma_{ep}(523 \text{ nm})$ and layer $\tau_p(523 \text{ nm})$ retrievals. Figure 13 shows that, apart from the small bias discussed above, the $\tau_p$ profiles start out at similar values at the top of the AATS-14 profiles and end a similar values at the bottom due to the MPL retrievals' anchoring. In between there are discrepancies, though, indicating that the $\sigma_{ep}$ are distributed differently over the vertical profile. This is apparent in Figure 12 where, compared to Nephelometer +PSAP $\sigma_{ep}(523 \text{ nm})$, MPLARM indicates lower $\sigma_{ep}(523 \text{ nm})$ in elevated layers above 3 km, but higher values below 2 km. This may be an effect of the MPL retrievals assuming that $S_p$ is altitude independent and/or due to inadequate corrections for overlap or afterpulse.

4 Results from Previous Campaigns

4.1 Aerosol Extinction from Scattering and Absorption Measurements

In numerous field campaigns since 1996 we have compared $\sigma_{ep}(\lambda)$ and layer $\tau_p(\lambda)$ obtained from Nephelometer+PSAP measurements with either AATS-6 or -14. As shown in Table 5, seven data sets from six field campaigns were reported in eight studies. The data sets were obtained aboard five different airplanes. Different metrics have been used in the eight studies to
describe the level of agreement making direct comparisons difficult. For each study we have re-
computed the coefficient of determination, $r^2$, and the relative bias differences in layer $\tau_p(\lambda)$. The
studies cover wavelengths between 450 and 700 nm. We find that with respect to AATS-14 (or -6) the layer $\tau_p(\lambda)$ value from Nephelometer+PSAP are biased low by -5 to -33%. The average low bias (all $\lambda$) is -17%.

Several studies have compared column integrated $\sigma_{ep}(\lambda)$ with ground-based Sun photometer
measurements of $\tau_p(\lambda)$ (Remer et al. [1997]; Kato et al. [2000]; Andrews et al. [2004]). Invariably they find the in-situ derived $\tau_p(\lambda)$ to be biased low with respect to the Sun photometer measurements. However, in all three studies assumptions about the aerosol above the maximum aircraft sampling altitude had to be made, humidification factors were not measured on the aircraft, and aircraft inlets were not suitable for sampling of larger aerosol particles.

4.2 Extinction calculated from airborne particle size distributions

In three campaigns since 1996 we have compared $\sigma_{ep}(\lambda)$ and layer $\tau_p(\lambda)$ calculated from
airborne measurements of particle size distributions with either AATS-6 or -14. As shown in
Table 6, excellent agreement was achieved in ACE-2 and ACE-Asia but poorer agreement
resulted from the TARFOX data set. While there is also a tendency for the $\sigma_{ep}(\lambda)$ and layer $\tau_p(\lambda)$
calculated from in situ data to be lower than the AATS-14 values, we observe the low bias found
in ACE-2 and ACE-Asia to be smaller than in the corresponding Nephelometer+PSAP comparisons listed in Table 5. However, the reverse is the case for the TARFOX data set.

To our knowledge, Clarke et al. [1996] present the only other study where layer
$\tau_p(\lambda)$ calculated from particle size distributions were compared to the values obtained with an
airborne sunphotometer (different from AATS). Good agreement was achieved for a profile
dominated by pollutant aerosol but the calculated $\sigma_{ep}(550 \text{ nm})$ values were 50% lower in a profile featuring an elevated Saharan dust layer.

4.3 Extinction from surface based and airborne lidars

In numerous campaigns we have compared $\sigma_{ep}(\lambda)$ and $\tau_p(\lambda)$ vertical profiles from one of the AATS instruments with surface-based or airborne lidars (see Table 7). The results involving seven different types of lidar systems have been published in 10 studies. Unfortunately we found it difficult to convert the results from all 10 studies into one quantitative metric. Therefore we use qualitative terms to describe the bias differences in $\sigma_{ep}(\lambda)$. As can be seen from Table 7, many comparisons result in small or no biases, however the biases that do occur are positive (i.e. lidar $\sigma_{ep}(\lambda)$ larger than AATS values).

Masonis et al. [2002] compared aircraft in situ and Raman lidar profiles of $\sigma_{ep}$ and 180° backscattering during the 1999 Indian Ocean Experiment (INDOEX). They found the lidar-derived values to be ~30% larger than the in situ-derived values. Petzold et al. [2002] report agreement within 30% (rms) for 180° backscattering measured with a six wavelength Raman/Mie lidar and calculated from airborne size distribution measurements during the Lindenberg Aerosol Characterization Experiment (LACE 98).

5 Summary and Conclusions

AIOP yielded one of the best measurement sets obtained to-date to assess our ability to measure the vertical profile of ambient aerosol extinction $\sigma_{ep}(\lambda)$. Extensive vertical profiling of the CIRPAS Twin Otter, carrying state-of-the-art aerosol and radiation instrumentation, over the heavily instrumented ARM CRF allowed us to compare 11 to 26 $\sigma_{ep}(\lambda)$ profiles obtained from 6 different instruments: airborne Sun photometer (AATS-14), airborne nephelometer plus
absorption photometer (Nephelometer+PSAP), airborne cavity ring-down system (Cadenza),
ground-based Raman lidar (CARL) and 2 ground-based elastic backscatter lidars (MPLARM and
MPLNET).

We find good agreement among the in-situ measurements, Cadenza and
Nephelometer+PSAP, on the Twin Otter aircraft. Averaged over 25 profiles, the Cadenza
\( \sigma_{\varepsilon p}(675\text{nm}) \) are higher by 6.6\% (bias difference) than the Nephelometer+PSAP values. This
represents a very successful demonstration of the first airborne application of the cavity-
ringdown method to measure \( \sigma_{\varepsilon p}(\lambda) \).

Subsequently we used the AATS-14 measurement of \( \tau_p(\lambda) \) and \( \sigma_{\varepsilon p}(\lambda) \) as a reference against
which we compared all other methods. This choice was driven by the fact that AATS-14 has the
largest spectral coverage and can match most of the other instruments’ wavelengths relatively
closely.

When compared to AATS-14 \( \sigma_{\varepsilon p}(\lambda) \), we find the in-situ measurements to be biased low
(0.002 – 0.004 km\(^{-1}\) equivalent to 12-17\% in the visible, or 44\% in the near-infrared). The low
bias is also apparent when considering layer \( \tau_p(\lambda) \). The statistical quantities we investigated
show that the differences (which should be considered modest, at least for the visible) are
proportional differences rather than systematic offsets. We also find the low bias to increase with
increasing wavelength.

On the other hand, we find that with respect to AATS-14, the \( \sigma_{\varepsilon p}(\lambda) \) values from all 3 lidars
are biased high: Bias differences are 0.004 km\(^{-1}\) (13\%) and 0.007 km\(^{-1}\) (24\%) for the two elastic
back-scatter lidars (MPLNET and MPLARM, \( \lambda=523 \text{ nm} \)) and 0.029 km\(^{-1}\) (54\%) for the Raman
lidar (\( \lambda=355 \text{ nm} \)). Unlike the differences found between AATS-14 and the in-situ measurements,
the differences between AATS-14 and the three lidars have the nature of an offset. This causes
the relative bias to decrease at larger $\sigma_{\text{sp}}(\lambda)$ (i.e. bias between AATS and CARL reduces to 10% if only $\sigma_{\text{sp}}(355 \text{ nm}) > 0.15 \text{ Km}^{-1}$ are considered [Ferrare et al., this issue]). An unnoticed loss of sensitivity of the Raman lidar had occurred leading up to AIOP, and we expect better agreement from the recently restored system. However, the present comparison between AATS-14 and CARL is valuable as it assesses the daytime retrievals of $\sigma_{\text{sp}}(355 \text{ nm})$ of a Raman lidar in an operational setting. CARL is the only Raman lidar in the world designed to autonomously provide a continuous day and nighttime 10-year data record [Turner et al., 2002].

We emphasize the assessment of the uncertainties in the AATS-14 retrieved quantities. The instrument was calibrated at the Mauna Loa Observatory (MLO), Hawaii, 1.5 months before and 1.5 months after the AIOP campaign and the calibration constants were fine tuned within the bounds of pre- and post-mission calibration by inspecting low $\tau_p(\lambda)$ spectra obtained near maximum flight altitude (5.6 km).

The in-flight performance of AATS-14 was assessed by comparing $\tau_p(\lambda)$ obtained during low level legs (~90 m) against ground-based Sun photometers. The level of agreement between AATS-14 and two AERONET Sun photometers is similar to what we found from low altitude fly-bys over AERONET sites in previous campaigns. The agreement with a third ground-based Sun photometer (NIMFR) is particularly good, in fact operating four Sun photometers (including AATS-6) side-by-side on the ground in previous ARM IOPs did not result in a higher level of agreement.

The robustness of the AATS-14 differentiated profiles of $\rho_w$ and $\sigma_{\text{sp}}(\lambda)$ were tested by comparing $\rho_w$ obtained from AATS-14 and the aircraft in situ sensors. This presumes that an aircraft in-situ measurement of $\rho_w$ is more straightforward than measuring ambient $\sigma_{\text{sp}}(\lambda)$. 30
Averaged over 35 vertical profiles we find a relative rms difference of 20% and a small bias difference of 5% (in situ $\rho_\omega - \text{AATS-14 } \rho_\omega$).

Because most of the errors in AATS-14 $\tau_p(\lambda)$ or CWV are of systematic nature, they cancel out when differences (such as layer $\tau_p(\lambda)$ or LWV) or differentiations ($\sigma_{ep}(\lambda)$ or $\rho_\omega$) are used. However, uncertainties in the AATS-14 $\sigma_{ep}(\lambda)$ profiles arise from horizontal and temporal variability in the overlying aerosol. For the 25 $\sigma_{ep}(\lambda)$ vertical profiles used here this resulted in average $\delta\sigma_{ep}(\lambda = 453, 519, 675, 1558 \text{ nm}) = 0.032, 0.029, 0.024, 0.014 \text{ Km}^{-1}$ equivalent to 101-176% if expressed as $\delta\sigma_{ep}(\lambda)/\sigma_{ep}(\lambda)$. The rms differences (other methods vs. AATS-14) in Table 3 are smaller than these uncertainties. One might therefore conclude that the $\sigma_{ep}(\lambda)$ measurements agree within the total error bars of AATS-14 alone. However, it is important to note, that the AATS-14 $\delta\sigma_{ep}(\lambda)$ represent random errors. It is possible to turn these random errors into bias errors for a single profile by flying a ramped ascent or descent under a pronounced aerosol gradient without changing heading. However, none of the profiles used in this study was acquired using such a flight pattern. Moreover, averaged over an ensemble of profiles (as done in this study) we can rule out a systematic bias due to spatial variability as this would require flying each profile with the pattern described above, under gradients with the same mathematical sign. The same discussion applies to the uncertainties of AATS-14 layer $\tau_p(\lambda)$ where, in fact, we observe differences that are often larger than the random errors (see Figure 10).

Hence, we believe the observed biases to be statistically significant. Furthermore, we find similar biases in the results published from previous field campaigns since 1996 involving AATS-6 or AATS-14:
Combining the results from AIOP with those from 5 previous field campaigns, we find airborne Nephelometer+PSAP measurements of layer $\tau_p(\lambda = 450-700nm)$ to be biased slightly low (5 - 33%, average of 17%) when compared to airborne Sun photometer (AATS-6 or -14) values.

From three previous campaigns we find layer $\tau_p(\lambda)$ calculated from airborne measurements of particle size distributions to be less than the AATS-6 or -14 values (average of 18%). However the data set for this computationally involved comparison is relatively small.

In 5 previous field campaigns we have compared $\sigma_{ep}(\lambda)$ and $\tau_p(\lambda)$ vertical profiles from one of the AATS instruments with surface based or airborne lidars. Many comparisons result in small or no biases, however the biases that do occur are positive (i.e. lidar $\sigma_{ep}(\lambda)$ larger than AATS values).

There is a clear tendency for the remote sensing methods, lidar and airborne Sun photometers, to yield larger $\sigma_{ep}(\lambda)$ and $\tau_p(\lambda)$ values than the in-situ methods. Adding the not previously used airborne cavity-ring-down technique (Cadenza instrument), did not significantly alter that tendency. In fact, Cadenza’s ability to in-situ measure $\sigma_{ep}$ at $\lambda=1550$ nm, highlights the spectral signature of the low bias (i.e. low bias with respect to AATS-14 increases with increasing wavelength). The low bias could be caused by particle sampling losses or incomplete corrections for shrinkage by evaporation of water, organics, or nitrates.

We cite numerous studies, with no AATS involved, that also found the remote sensing methods (lidar and Sun photometers) to yield larger $\sigma_{ep}(\lambda)$ or $\tau_p(\lambda)$ values than the in-situ methods.

Unknown gaseous absorption in the atmosphere (as postulated by Halthore et al. [1998]), not accounted for in the analysis of the Sun photometer and lidar data, could also lead to the
observed biases. However, Mlawer et al. [2000] provide “strong evidence that in this spectral range [350-1000 nm] there are no unmodeled molecular absorbers of significance to the atmospheric energy balance.”

While we find that each of the methods investigated here has its strengths and weaknesses, there is no definitive proof that one of the methods is fundamentally flawed. From the biases found in AIOP and previous studies, we conclude that the systematic error associated with measuring the tropospheric vertical profile of the ambient aerosol extinction with current state-of-the art instrumentation is 15-20% at visible wavelengths and potentially larger in the UV and near-infrared. Random errors, as measured by rms differences (e.g. Table 3), are considerably larger, ranging from 26% to 98%.

Acknowledgments: The Atmospheric Radiation Measurement (ARM) Program is sponsored by the U.S. Department of Energy, Office of Science, Office of Biological and Environmental Research, Environmental Sciences Division. The success of the Aerosol IOP was due to the hard work and dedicated efforts from a large team of scientists and investigators from National Laboratories and Universities, CIRPAS Twin Otter and Cessna pilots, crew and support personnel, SGP site personnel, ARM infrastructure support, weather forecaster, and support from Greenwood aviation at Ponca City airport. We thank ARM for the support of this IOP. This research was also supported by a grant form the NOAA Office of Global Programs. EJW and MPLNET are supported by the NASA Radiation Sciences Program and Earth Observing System. The authors would like to thank Jack Ji for operating AERONET and MPLNET instrumentation.

Aerosol Optical Depth
How well can we measure the vertical profile of tropospheric aerosol extinction?

Authors:

Submission to: Journal of Geophysical Research - Atmospheres

The recent Department of Energy Atmospheric Radiation Measurement (ARM) Aerosol Intensive Operations Period (AIOP, May 2003) yielded one of the best measurement sets obtained to-date to assess our ability to measure the vertical profile of ambient aerosol extinction $\sigma_v(\lambda)$ in the lower troposphere. During one month, a heavily instrumented aircraft with well characterized aerosol sampling ability carrying well proven and new aerosol instrumentation, devoted most of the 60 available flight hours to flying vertical profiles over the heavily instrumented ARM Southern Great Plains (SGP) Climate Research Facility (CRF). This allowed us to compare vertical extinction profiles obtained from 6 different instruments: airborne Sun photometer (AATS-14), airborne nephelometer/absorption photometer, airborne cavity ring-down system, ground-based Raman lidar and 2 ground-based elastic backscatter lidars. We find the in-situ measured $\sigma_v(\lambda)$ to be lower than the AATS-14 derived values. Bias differences are $0.002 - 0.004$ Km$^{-1}$ equivalent to 12-17% in the visible, or 45% in the near-infrared. On the other hand, we find that with respect to AATS-14, the lidar $\sigma_v(\lambda)$ are higher: Bias differences are $0.004$ Km$^{-1}$ (13%) and $0.007$ Km$^{-1}$ (24%) for the two elastic back-scatter lidars (MPLNET and MPLARM, $\lambda=523$ nm) and $0.029$ Km$^{-1}$ (54%) for the Raman lidar ($\lambda=355$ nm). An unnoticed loss of sensitivity of the Raman lidar had occurred leading up to AIOP and we expect better agreement from the recently restored system.

Looking at the collective results from 6 field campaigns conducted since 1996, airborne in situ measurements of $\sigma_v(\lambda)$ tend to be biased slightly low (17% at visible wavelengths) when compared to airborne Sun photometer $\sigma_v(\lambda)$. On the other hand, $\sigma_v(\lambda)$ values derived from lidars tend to have no or positive biases.

From the bias differences we conclude that the typical systematic error associated with measuring the tropospheric vertical profile of the ambient aerosol extinction with current state-of-the-art instrumentation is 15-20% at visible wavelengths and potentially larger in the UV and near-infrared.
