ABSTRACT

We present the first combined study of the recently discovered source IGR J16283–4838 with Swift, INTEGRAL, and RXTE. The source, discovered by INTEGRAL on April 7, 2005, shows a highly absorbed (variable \( N_H = 0.4 - 1.7 \times 10^{23} \text{ cm}^{-2} \)) and flat (\( I \sim 1 \)) spectrum in the Swift/XRT and RXTE/PCA data. No optical counterpart is detectable (\( V > 20 \text{ mag} \)), but a possible infrared counterpart within the Swift/XRT error radius is detected in the 2MASS and Spitzer/GLIMPSE survey. The observations suggest that IGR J16283–4838 is a high mass X-ray binary containing a neutron star embedded in Compton thick material. This makes IGR J16283–4838 a member of the class of highly absorbed HMXBs, discovered by INTEGRAL.

Subject headings: gamma rays: observations — X-rays: binaries — X-rays: individual (IGR J16283–4838) — stars: neutron

1. Introduction

Star formation in our Galaxy takes place mainly in the dense regions of the spiral arms. These regions host massive molecular clouds and also the majority of the single and binary neutron stars (\( \sim 10^6 \)) and black holes (\( \sim 10^8 \)) in the Milkyway. The dense molecular clouds lead to strong star for-
coded FOV) and the spectrograph SPI (Vedrenne et al. 2003; 35° × 35°, PCFOV), and its observing program focussed on the Galactic plane and center, INTEGRAL is a powerful tool to discover highly absorbed sources ($N_H > 10^{23}$ cm$^{-2}$) in the Galactic plane. So far a handful of those enigmatic objects has been found since the launch of INTEGRAL in October 2002\(^1\). Six of those sources have been published so far: IGR J16318–4848 (Walter et al. 2003) with an absorption of $N_H \approx 19 \times 10^{23}$ cm$^{-2}$ (Matt & Guainazzi 2003), IGR J19140+0951 ($N_H = 0.3 - 1.0 \times 10^{23}$ cm$^{-2}$; Rodriguez et al. 2005), IGR J16320–4751 ($N_H \approx 2 \times 10^{23}$ cm$^{-2}$; Rodriguez et al. 2003), IGR J16393–4643 ($N_H \approx 10^{23}$ cm$^{-2}$, Combi et al. 2004), IGR J16358–4726 ($N_H \approx 4 \times 10^{23}$ cm$^{-2}$, Patel et al. 2004), and IGR J16479–4514 ($N_H > 5 \times 10^{23}$ cm$^{-2}$, Walter et al. 2004). While the nature of the latter source is still unknown, the other sources appear to be HMXBs, probably hosting a neutron star as the compact object. Most, if not all, of these sources show variable absorption. In this paper we report the discovery and analysis of another highly absorbed source, IGR 516283–4838 (Soldi et al. 2005). This work makes the first use of the combined data of INTEGRAL, Swift, RXTE, and Spitzer.

2. Observations of IGR J16283–4838

All observations discussed in this Section are summarized in Table 1.

2.1. Discovery by INTEGRAL

IGR J16283–4838 was discovered (Soldi et al. 2005) during the observation of the Norma arm region by the imager IBIS/ISGRI (Lebrun et al. 2003) on-board INTEGRAL. The observation lasted from April 7, 2005, 13:57 U.T. until April 9, 4:44 U.T. with an effective ISGRI exposure time of 126 ksec. The source position was revealed to be $R.A. = 16^h28^m3.3^s$, $DEC = -48^\circ38'3$ (J2000.0) with 3 arcmin uncertainty. The source showed a flux of $f_X = (4.8 \pm 0.8) \times 10^{-11}$ erg cm$^{-2}$ s$^{-1}$ in the 20 - 60 keV band. No emission was detectable above 60 keV. From the analysis of another ISGRI observation with similar exposure time we estimate the 3σ upper limit in the 60 - 200 keV band $f_X < 1.2 \times 10^{-10}$ erg cm$^{-2}$ s$^{-1}$. The analysis of the data prior to the discovery lasting from April 4, 01:55 U.T. until April 6, 11:24 U.T., with an exposure time of 192 ksec resulted in a 3σ upper limit of $f_{20-60}$ keV $= 1.7 \times 10^{-11}$ erg cm$^{-2}$ s$^{-1}$. The source showed significant brightening during an INTEGRAL observation starting on April 10, 1:26 U.T. Even though IGR J16283–4838 was in the partially coded field of view of IBIS, the analysis gave a 11.6σ detection within 96 ksec with a flux of $f_{20-60}$ keV $= (11.3 \pm 1.0) \times 10^{-11}$ erg cm$^{-2}$ s$^{-1}$ (Paizis et al. 2005). The low flux level of the source did not allow the extraction of a spectrum from the ISGRI data and no simultaneous soft-X and optical observations are available as IGR J16283–4838 was always outside the field of view of INTEGRAL's X-ray monitor JEM-X and of the optical monitor OMC. No further INTEGRAL observations of the source were obtained.

2.2. X-ray follow-up observations

After the discovery of IGR J16283–4838 a Swift follow-up observation was requested in order to obtain an X-ray spectrum and an optical measurement. The Swift mission (Gehrels et al. 2004) is a multiwavelength observatory for gamma-ray-burst astronomy. The payload combines a gamma-ray instrument (Burst Alert Telescope, 15 - 150 keV; Barthelmy et al. 2005), an X-ray telescope (XRT; Burrows et al. 2005), and a UV-optical telescope (UVOT; Roming et al. 2005). The XRT is a focussing X-ray telescope with a 110 cm$^2$ effective area, 23 arcmin FOV, 18 arcsec resolution, and 0.2-10 keV energy range. The UVOT design is based on the Optical Monitor (OM) on-board ESA’s XMM-Newton mission, with a field of view of 17 × 17 arcmin and a pixel size of 4 × 4 arcsec on the sky.

Two Swift observations took place 3 and 5 days after the last INTEGRAL observation. The first one started on April 13, 14:02 U.T. with an exposure time of 2.5 ksec, which resulted in an effective Swift/XRT exposure of 550 sec. A preliminary analysis of the XRT data refined the position of IGR J16283–4838 to $R.A. = 16^h28'10.7''$, $DEC = -48^\circ38'55''$ (J2000.0) with an estimated uncertainty of 5 arcsec radius (Kennea et al. 2005).

A second observation was performed on April 15, 00:16 U.T. with 2600 sec effective XRT ex-
posure time. For our analysis of the Swift data we used the calibration files which have been released on April 5, 2005 and the software provided by the Swift Science Center. These tools are included in the release of HEASoft 6.0 as of April 12, 2005. Applying a centroid algorithm to the data of April 15 gives a refined position for the source of R.A. = $16^h28^m10.56^s$, DEC = $-48°38'56.4''$ with an uncertainty of 6 arcsec radius, consistent with both the preliminary analysis and the INTEGRAL measurement. The spectrum extracted from the XRT data of April 15 is shown in Fig. 1. The spectral fitting was done using version 11.3.2 of XSPEC (Arnaud 1996).

Both XRT spectra are well represented by an absorbed power law with the same photon index ($\Gamma = 1.12 \pm 0.35$), but different absorption column density. The spectrum of April 13 shows less absorbed ($N_H = 0.6^{+0.4}_{-0.2} \times 10^{23}$ cm$^{-2}$) spectrum with a lower flux ($f_{2-10\,\text{keV}} = (3.9 \pm 0.3) \times 10^{-11}$ erg cm$^{-2}$ s$^{-1}$) than the April 15 one. The latter data show $N_H = 1.7^{+0.4}_{-0.1} \times 10^{23}$ cm$^{-2}$ and a flux in the 2 - 10 keV band of $f_{2-10\,\text{keV}} = (2.7 \pm 0.3) \times 10^{-11}$ erg cm$^{-2}$ s$^{-1}$. The data are equally well fit by an absorbed black body with $N_H = 0.3/1.4 \times 10^{23}$ cm$^{-2}$ (April 13/15) with a temperature of $kT = 2.0 \pm 0.3$ keV. Adding a Gaussian line to the fit does not improve the results significantly. The 3$\sigma$ upper limit for the Fe Kα line at 6.4 keV is $4 \times 10^{-4}$ ph cm$^{-2}$ s$^{-1}$. Because of the short exposure time the source was not detected by the BAT instrument.

IGR J16283-4838 was then also observed twice by RXTE using the Proportional Counter Array (PCA). The first observation starting on April 14, at 0:46 U.T. lasted 3.6 ksec, the second on April 15, at 16:07 U.T. lasted 2.9 ksec (Markwardt et al. 2005). The RXTE/PCA has a large field of view (2° FWZM). For targets near the Galactic plane, a significant amount of Galactic diffuse emission enters the PCA aperture, which is considered background. This background was modeled by taking a nearby observation of the Galactic plane (observation 91409-01-02-00, $l = 341.4°, b = 0.6°$). This observation is at a similar latitude as IGR J16283-4838, so the diffuse emission should have nearly the same spectrum. The background observation was modeled as thermal bremsstrahlung with a temperature of $kT = 7.4$ keV, plus line emission at $\sim 6.5$ keV with an equivalent width of 600 eV. The shape of the background template was fixed and added to the spectral model of the two PCA observations of IGR J16283-4838; only the total normalization of the template was allowed to vary. The best fit models for the source are shown in Table 1.

No pulsations are detectable in the PCA data.

2.3. Infrared and optical data

Within the 6 arcsec error radius around the refined position determined from the Swift/XRT data the infrared source 2MASS J16281083-4838560 is located at 2.7 arcsec distance (Rodriguez & Paizis 2005). This source has K, J, and H band magnitudes of $K = (13.95 \pm 0.06)$ mag, $J > 16.8$ mag, and $H > 15.8$ mag (95% lower limits).

The Galactic Legacy Infrared Midplane Survey Extraordinaire (GLIMPSE2; Benjamin et al. 2003) data show the source SSTGLMC G335.3268+00.1016 at 2.9 arcsec distance to the XRT position, consistent with the 2MASS detection. GLIMPSE is a 4-band near- to mid-infrared survey by Spitzer (Werner et al. 2004) of the inner two-thirds of the Galactic disk with a spatial resolution of $\sim 2''$. The Infrared Array Camera (Fazio et al. 2004) imaged 220 square degrees at wavelengths centered on 3.6, 4.5, 5.8, and 8.0 $\mu$m in the Galactic longitude range 10° to 65° on both sides of the Galactic center and in Galactic latitude $\pm 1°$. The Spitzer/GLIMPSE data show a clear detection of IGR J16283-4838 in all four energy bands (Tab. 1).

Within the error radius of IGR J16283-4838 no optical counterpart is detectable on the POSS-II plates of the Digitised Sky Survey. During the observations by Swift on April 13 and on April 15 the UVOT took an image in the V-band. No source is detected within the error radius down to a magnitude of $V > 20$ mag. The image extracted from the Swift/UVOT data on April 15 is shown in Fig. 2. The contours indicate the XRT count map.

3. Spectral Energy Distribution

The spectral energy distribution (SED) of IGR J16283-4838 is shown in Fig. 3. In the
chosen diagram a single power law with photon index $\Gamma = 2$ would appear as an even, horizontal line. Note that we display in the SED the absorbed fluxes as they are measured at the observer. No error bars have been included for the Swift/XRT data and only the XRT data of April 15 are shown for better visibility. From the comparison of the XRT data points with the measurements by RXTE/PCA it is apparent that the XRT measurement was done during a high state of the source, while the RXTE/PCA and the two INTEGRAL/ISGRI measurements describe a lower flux state. Unfortunately the 60 – 200 keV upper limit does not constrain the SED significantly. Although not simultaneous, the mid-infrared (Spitzer), near infrared (2MASS), and the optical upper limit (Swift/UVOT) describe a sharp turnover in this energy region.

4. Discussion

The new hard X-ray source IGR J16283–4838 exhibits several characteristic features:

- IGR J16283–4838 is located at Galactic longitude $l = 335.3^\circ$ and latitude +6.1 arcmin in the Norma arm region
- It shows a strong flare within a time scale of days
- It shows absorption of the order of $N_H = 0.4 – 1.7 \times 10^{23} \text{ cm}^{-2}$ and a flat X-ray spectrum ($\Gamma \approx 1$)
- The bimodal spectral energy distribution has one peak in the mid-infrared and the other in the hard X-rays
- The flux of the iron $K\alpha$ line is $f_{K\alpha} < 4 \times 10^{-4} \text{ ph cm}^{-2} \text{ s}^{-1}$
- The optical counterpart is apparently weak ($V > 20 \text{ mag}$)

Combining this information enables us to put constraints on the nature of the source. The position within the Galactic plane at only +6.1 arcmin makes a Galactic origin of the source likely, even though some AGN have been seen through the plane by INTEGRAL, like the Seyfert 1 galaxy GR 734-292 (Marti et al. 1998; Sazonov et al. 2004). But a typical Seyfert 1 or Seyfert 2 can be ruled out as a counterpart for IGR J16283–4838, because of the strong variability. This would still leave the possibility of a blazar as counterpart. But the characteristic SED of blazars usually exhibits the gap between the synchrotron emission and the inverse Compton emission in the energy band where INTEGRAL/ISGRI is operating. The only class of blazars that peak in this energy range are the high-frequency peaked BL Lac objects. But even the brightest of those BL Lacs have not been detected so far by INTEGRAL. Also, the absorption by the Galaxy in the direction of the source ($N_H = 2.2 \times 10^{22} \text{ cm}^{-2}$) is not high enough to explain the intrinsic absorption of $1.7 \times 10^{23} \text{ cm}^{-2}$, and thus intrinsic strong absorption in the BL Lac would be required to explain the Swift/XRT spectrum, but this has not been seen so far in blazar spectra.

If we consider IGR J16283–4838 to be a Galactic source, mainly two types of bright and variable hard X-ray emitters are likely to be a counterpart: Low Mass and High Mass X-ray Binaries, LMXBs and HMXBs, respectively. The hard X-ray spectrum with strong absorption indicates the presence of a HMXB in which no pulsation have been detected so far (Markwardt et al. 2005). Also the bright infrared emission indicates a massive star as the companion of the compact object.

For a HMXB it is likely that IGR J16283–4838 is located close to a star forming region in a Galactic spiral arm. Along the line of sight towards the source several arms are located (Russell 2003): The Sagittarius-Carina arm (0.7 kpc), the Scutum-Crux arm (3.2 kpc), the Norma-Cygnus arm (4.8 kpc), a star-forming region (7 kpc), and the Perseus arm (10.8 kpc). The luminosity of the object during the flare can be estimated by taking the brightest stage during the RXTE observation and assuming a distance to the object between 1 and 10 kpc. The unabsorbed flux is in this case only 20% larger than the absorbed one, because the significant part of the luminosity is emitted in the hard X-rays. The bolometric luminosity is then in the range $\log L_{\text{burst}} = 34.0 – 36.5$ (where $L$ is in units of erg s$^{-1}$). The quiescent luminosity of the system is at least a factor of $\sim 20$ lower with $\log L_q < 33 – 35.2$. This range of values is consistent with measurements from known Be/X-ray binaries with a neutron star as the compact object.
In any case the luminosity is far below the Eddington luminosity of a neutron star of $1.4M_\odot$ ($L = 1.8 \times 10^{38}$ erg s$^{-1}$).

The properties of IGR J16283-4838 are similar to those of a number of highly absorbed sources ($N_H = 1 - 20 \times 10^{23}$ cm$^{-2}$) found in the Galactic plane, especially in the Norma arm region (Walter et al. 2004). The HMXB IGR J19140+0951 shows also strong variable absorption (Rodriguez et al. 2005), indicating intrinsic absorption in the source. The observed properties of IGR J16283-4838 are consistent with those of IGR J19140+0951 in the bright state, where the iron line flux decreased to $4 \times 10^{-4}$ ph cm$^{-2}$ s$^{-1}$, which is at the upper limit for the Swift/XRT measurement in our case. The (non-)variability of the absorption in IGR J16318-4848 is still under discussion, as Walter et al. (2003) claim constant absorption, whereas Revnivtsev (2003) discovered variable absorption which could be connected with the orbital phase of the binary system. Only one of the newly detected highly absorbed sources has been claimed so far not to be a HMXB. Patel et al. (2004) observed IGR J16358-4726 with Chandra. From the X-ray data they favour the source to be a millisecond pulsar LMXB even though the HMXB interpretation cannot be ruled out completely, though it would require some unknown kind of spin-down torque to prevent the neutron star from spinning up in this particular case.

X-ray binaries with strong intrinsic absorption have been known already before INTEGRAL, for example in 4U 1700-377, GX 301-2, Vela X-1, and CI Cam. Except for the latter one, where the nature of the source is unclear to date, these sources are also HMXBs, likely to host a neutron star as the compact object. Vela X-1 shows variable absorption from a negligible value up to $7 \times 10^{23}$ cm$^{-2}$ (Pan et al. 1994). GX 301-2 shows strong absorption variation (up to $12 \times 10^{23}$ cm$^{-2}$; White & Swank 1984), and so does CI Cam ($(0.02 - 5) \times 10^{23}$ cm$^{-2}$; Boirin et al. 2002). In 4U 1700-377 the absorption is linked to the state of the HMXB system and varies by a factor of 2 between 0.9 and $2.0 \times 10^{23}$ cm$^{-2}$ (Boroson et al. 2003). It appears that variable absorption is a common feature in highly absorbed HMXBs. This could mean that the absorbing material is linked to the existence of a high mass donor in the binary system. In this case a strong and dense stellar wind ($10^{-7}$ to $10^{-8} M_\odot$ yr$^{-1}$) from the early-type stellar companion will probably cause the absorption in the system. The fact that all the absorbed sources so far have shown to be HMXBs (Walter et al. 2004) containing neutron stars does not rule out significant contribution of HMXBs with a black hole as the compact object. But these systems are expected to be less numerous than the neutron star HMXBs by a factor of 10 to 100, making the detection of a black hole binary within a sample of only about 10 detected highly absorbed HMXBs unlikely. These absorbed binary systems might provide a significant contribution to the Galactic hard X-ray background at energies above 10 keV (Lebrun et al. 2004; Valinia et al. 2000).

5. Conclusions

The newly discovered hard X-ray source IGR J16283-4838, located in the Norma arm region, is likely to be a HMXB containing a neutron star as the compact object. It is located in the Galactic Plane in the direction of star forming regions in the spiral arms and shows a large flare, which makes an extragalactic origin unlikely. The spectrum is hard ($\Gamma \sim 1$) and strongly absorbed during the flare, which indicates a HMXB rather than a LMXB. The luminosity is comparably low ($L < 10^{37}$ erg s$^{-1}$) which is typical for a neutron star HMXB. The strong and variable absorption ($N_H = 0.4 - 1.7 \times 10^{23}$ cm$^{-2}$) indicates that IGR J16283-4838 belongs to the class of highly absorbed HMXBs discovered by INTEGRAL along the Galactic plane. Bright and absorbed sources like IGR J16283-4838 could contribute significantly to the Galactic hard X-ray background in the 10–200 keV band.

It has to be pointed out that the discovery and classification of IGR J16283-4838 would not be possible without combining the observations of the recent observatories in space, like INTEGRAL, Swift, RXTE, and Spitzer. Combined efforts from these missions should lead to deeper insights into the nature of the hard X-ray source population in our Galaxy in the near future.

We like to thank John Greaves for pointing out the GLIMPSE data. This work is based in part on observations made with the Spitzer Space
Telescope, which is operated by the Jet Propulsion Laboratory, California Institute of Technology under NASA contract 1407. This research has made use of the SIMBAD Astronomical Database which is operated by the Centre de Données astronomiques de Strasbourg.
