Abstract

GLACE is a model intercomparison study focusing on a typically neglected yet critical element of numerical weather and climate modeling: land-atmosphere coupling strength, or the degree to which anomalies in land surface state (e.g., soil moisture) can affect rainfall generation and other atmospheric processes. The twelve AGCM groups participating in GLACE performed a series of simple numerical experiments that allow the objective quantification of this element. The derived coupling strengths vary widely. Some similarity, however, is found in the spatial patterns generated by the models, enough similarity to pinpoint multi-model “hot spots” of land-atmosphere coupling. For boreal summer, such hot spots for precipitation and temperature are found over large regions of Africa, central North America and India; a hot spot for temperature is also found over eastern China. The design of the GLACE simulations are described in full detail so that any interested modeling group can repeat them easily and thereby place their model’s coupling strength within the broad range of those documented here.
1 Introduction

1.1 Motivation

Precipitation has a clear impact on soil moisture: large rain events tend to wet the soil. To what extent, though, do land surface moisture and temperature states affect in turn the evolution of weather and the generation of precipitation? How does a human-induced change in land cover affect local and remote weather, if at all? Such questions lie at the heart of much recent climatological research. This research is largely performed with numerical models of weather and climate (atmospheric general circulation models, or AGCMs, and mesoscale models), mostly because direct observations of the impact of land surface anomalies on atmospheric behavior are difficult, if not impossible, to obtain at regional to continental scales. Also, AGCMs and mesoscale models have the advantage of being amenable to sensitivity studies – their process parameterizations can be manipulated easily in controlled experiments.

The list of published AGCM studies that address questions of land-climate interaction is extensive (e.g., Charney et al., 1977; Shukla and Mintz, 1982; Henderson-Sellers and Gornitz, 1984; Delworth and Manabe, 1989; Oglesby and Erickson, 1989; Dirmeyer, 1994; Lau and Bua, 1998; Xue et al., 2001, 2004; to name only a small fraction). Generally missing from these studies, however, is an analysis of the degree to which the experimental results are model-dependent. Such model dependence can bias results tremen-
dously. Consider two hypothetical AGCMs, one in which the atmosphere responds strongly to anomalies in surface fluxes, which in turn respond to anomalies in land surface state, and one in which the atmosphere has an internal variability (chaotic dynamics) that overwhelms any signal from the land surface. (Note that in this paper, the term 'land surface' refers to the combination of the vegetation canopy, the soil-atmosphere interface, and the top few meters or so of the soil, as typically modeled by AGCMs.) Experiments with these two AGCMs would lead to contradictory conclusions about the importance of properly initializing soil moisture in forecast simulations, about the degree to which deforestation affects climate, and perhaps even about the need for a realistic treatment of land surface processes in climate simulations. Contradictory results regarding land-atmosphere interaction do pervade the literature; see, for example, the broad range of results on deforestation outlined by Hahmann and Dickinson (1997).

The degree to which the atmosphere responds to anomalies in land surface state in a consistent manner, particularly at daily to seasonal timescales, is hereafter loosely referred to as the "land-atmosphere coupling strength". Coupling strength cannot be determined a priori from a look at the model's computer code. It is not explicitly prescribed or parameterized; it is rather a net result of complex interactions between numerous complex process parameterizations in the AGCM, such as those for evapotranspiration, boundary layer development, and moist convection. Arguably, a shortcoming in the
analysis of the model-generated climate system is that this coupling strength, though a fundamental element of the system, is rarely examined closely and is almost never objectively quantified. The great majority of AGCM land-atmosphere interaction studies do not address the realism of the coupling strength implicit in the model used or how it compares with that in other models.

An objective quantification and documentation of the coupling strength across a broad range of models would be valuable, if only to serve as a frame of reference when interpreting the experimental results of any particular model. This objective documentation and quantification is indeed the goal of GLACE (for Global Land-Atmosphere Coupling Experiment). GLACE aims to show the extent to which coupling strength varies between models, and, more importantly, to characterize individual models as having a relatively strong, intermediate, or weak coupling, for later use in interpreting various results obtained with those models. The range of coupling strengths uncovered by GLACE serves to quantify the uncertainty inherent in our understanding of land-atmosphere coupling and our ability to model it.

1.2 Relationship to Pilot Study

GLACE is a broad follow-on to the four-model intercomparison study of Koster et al. (2002), hereafter referred to as K02. K02 describes a numerical experiment performed by four independent AGCM modeling groups, an
experiment that quantified, for each of the models, the degree to which precipitation responds consistently to a prescribed, model-consistent time-series of land surface prognostic states. The chief result of KO2 was a marked disparity in the coupling strengths of the four models.

GLACE extends the KO2 study substantially:

- Participation From a Wider Range of Models. The intriguing inter-model variations discovered by KO2 are presumably indicative of a broad range of coupling strengths implicit in today's AGCMs. The goal of GLACE is to establish this range more precisely and (more importantly) to generate a comprehensive "table" of AGCM coupling strengths, a table that can help in the interpretation of the published results of a wide variety of climate models.

- Separation of the Effects of "Fast" and "Slow" Reservoirs. The experimental set-up used in KO2 was limited; the prescribed diurnal surface temperature variations appeared to have had as much an effect on coupling strength as anything else. Since the initialization of surface temperature and water amounts in "fast" moisture reservoirs (e.g., canopy interception) have little potential for prediction, particularly at subseasonal timescales and longer, the differences uncovered by KO2 may have limited practical application. Of much
greater relevance to many land impact questions is whether some of the "slower" state variables — those variables with significant "memory" (in particular, soil moisture in the root zone and deeper reservoirs) — have an impact on the evolution of weather. This aspect of coupling strength is a major focus of GLACE.

- **Effect on Air Temperature.** K02 focused on how the land surface boundary affects the generation of precipitation. Also of interest is the control of the land boundary on air temperature fluctuations, particularly when only root zone (and lower) soil moisture is prescribed. GLACE provides the means to address this issue.

- **Correction of Miscellaneous Technical Issues.** Numerous technical problems were encountered during the K02 study. Appropriate corrections are incorporated into the design of GLACE. The resulting model intercomparison is, as a result, cleaner.

GLACE can indeed claim participation from a wider range of models. The experiment was offered to the community in early 2003. Over the course of that year, twelve AGCM groups performed the experiment and submitted results for processing.
1.3 Focus of Paper

The purpose of the present paper is twofold. First, it thoroughly describes and contrasts the inherent coupling strengths of the twelve participating models. It thus provides a "snapshot" of the current state of land-atmosphere modeling, with emphasis (unlike K02) on the impacts of the slow reservoirs relevant to seasonal prediction. Second, and perhaps more important, it provides a full set of instructions for performing the experiments. This will allow additional models or future versions of the participating models to repeat them at will and immediately place their model's behavior in the context of the behaviors documented here. A companion paper (Guo et al., this issue) examines the model-to-model differences in coupling strength—and the spatial variations in coupling strength seen within a given model—in the context of parameterization differences and differences in climatological and hydrological regime.

Neither paper, however, addresses the realism of simulated coupling strength, primarily because direct measurements of land-atmosphere interaction at large scales do not exist. The identification of the proper measurements to make and their subsequent collection and analysis would clearly advance the study of this interaction. Potential local assessments of coupling strength and indirect large-scale evaluations are reserved for a future study.

In the present paper, the experimental design is described in section 2, with technical details relegated to an appendix. Section 3 provides an
overview of the participating models. Section 4 presents the basic results, and Section 5 provides a look at where on the globe the models tend to agree.

2 Experimental Design

2.1 Overall Framework

The GLACE experiments consist of three separate 16-member ensembles of AGCM simulations, each simulation covering the period June 1 - August 31. In CPU terms, this is equivalent to a single 12-year AGCM simulation. The overall design of the experiments is illustrated in Figure 1, and the run specifications are summarized in Table 1.

The first ensemble, called Ensemble W, is essentially a standard set of AGCM simulations with prescribed sea surface temperatures. The only unusual aspect of this ensemble is that in one of the simulations, chosen randomly but referred to here as "W1" for convenience, all land prognostic variables are recorded into a special data file at every time step. (See top panel of Figure 1.) The special data file is hereafter referred to as W1STATES. The recorded prognostic variables include soil moisture contents at all vertical levels, temperatures at all vertical levels, canopy interception reservoir content, and various variables characterizing snow, if snow is present. One global field is recorded per state variable per time step. K02, by the way, demonstrated that the choice of the ensemble member used to write into W1STATES is unimportant (at least for the one model examined); on a global average, any
ensemble member should produce approximately the same results in the later parts of the experiment.

The second part of the experiment consists of another 16-member ensemble of 3-month simulations, using the same prescribed SSTs and the same 16 sets of atmospheric initial conditions. In this ensemble (hereafter referred to as Ensemble R), all member simulations are forced to maintain precisely the same time series of (geographically-varying) land surface states – namely, the states generated in simulation W1. If for example, simulation W1 produced a very wet soil in southern France on July 27, then the atmosphere in every simulation of ensemble R is forced to feel the same very wet soil in southern France on July 27. This effect is achieved by discarding, at every time step of every R simulation, the updated values of all land surface prognostic variables and then replacing them with the corresponding values for that time step from W1 STATES. (See middle panel of Figure 1.)

The final part of the experiment, referred to as ensemble S, is equivalent to ensemble R except that only a small subset of the land surface prognostic variables are reset at each time step, as illustrated in the bottom panel of Figure 1. In particular, only soil moistures corresponding to soil layers with centers 5 cm or more below the surface are reset from W1 STATES. The other variables (e.g., temperatures, canopy interception contents, and soil moisture in a thin surface layer, if such a layer exists) are allowed to evolve freely, as they did in ensemble W. Most of the analysis in this paper and the
companion paper will focus on ensemble S, since it isolates and quantifies the impact of a relatively predictable state (deep soil moisture, a state with significant memory [Koster and Suarez, 2001]) on the evolution of weather.

SST boundary conditions for all of the integrations correspond, as much as possible, to the period June-August 1994. This year was chosen because neither El Niño nor La Niña conditions during the year are strong. Different SST datasets are available, but for consistency, modeling groups were asked to use the AMIP-2 SST dataset (Gleckler, 1996) if at all possible. The KO2 study, by the way, suggests that the impact of the chosen SST field on overall land-atmosphere coupling strength is small, though the choice of the year may perhaps have some bearing on specific geographical details.

Specific details of the experimental design, including rules for initialization of the different ensemble members, are provided in Appendix A.

3 Participating Models

Twelve AGCMs participated in the experiment. They are labeled as follows: BMRC, for the Bureau of Meteorology Research Centre in Melbourne, Australia; CCCma, for the Meteorological Service in Toronto, Canada; CCSR/NIES, for the Center for Climate System Research/National Institute for Environmental Studies in Tokyo, Japan; COLA, for the Center for Ocean-Land-Atmosphere Studies in Calverton, Maryland, United States; CSIRO-CC3, for the Commonwealth Scientific and Industrial Research Organization in
Aspendale, Victoria, Australia; GEOS-CRB, an AGCM used in the Climate and Radiation Branch at the Goddard Space Flight Center in Greenbelt, Maryland, United States; GFDL, for the Geophysical Fluid Dynamics Laboratory in Princeton, New Jersey, United States; HadAM3, an AGCM used at the Hadley Centre for Climate Prediction and Research in Exeter, United Kingdom; CAM3, for the Community Atmosphere Model (version 3) used at the National Center for Atmospheric Research in Boulder, Colorado, United States; GFS/OSU, which stands for “Global Forecast System model coupled to the Oregon State University land surface model”, used at the National Center for Environmental Prediction in Camp Springs, Maryland, United States; NSIPP, for the NASA Seasonal-to-Interannual Prediction Project, now part of the Global Modeling and Assimilation Office at the Goddard Space Flight Center in Greenbelt, Maryland, United States; and UCLA, for the University of California at Los Angeles, United States. Table 2 lists important details regarding the implementation of each of these models.

4 Results

4.1 Precipitation

Using the $\Omega$ diagnostic defined by K02, we examine here the land surface’s control on “synoptic-scale” precipitation variability, that is, the variability of precipitation on timescales of about a week. First, we aggregate the precipitation output from each simulation into time-series of 6-day totals. Given
that the simulations are 92 days long and that we ignore the first 8 days to avoid problems associated with initial "shocks" to the modeled atmosphere, each simulation provides a time series, $P(t)$, consisting of fourteen 6-day totals. For a given ensemble, which consists of 16 simulations, the standard deviation of precipitation, $\sigma_P$, is computed across the resulting 224 6-day totals. (The choice of 6 days for the time-aggregation is arbitrary; other choices give similar results.)

Next, we compute the ensemble mean time series, $\bar{P}(t)$:

$$\bar{P}(t) = \frac{1}{16} \sum_{i=1}^{16} P_i(t),$$  \hspace{1cm} (1)

where $i$ represents the index of the ensemble member. The fourteen values in $\bar{P}(t)$ are used to compute the standard deviation of the ensemble mean time series, $\sigma_{\bar{P}}$. Finally, $\sigma_P$ and $\sigma_{\bar{P}}$ are combined into the diagnostic $\Omega_P$:

$$\Omega_P = \frac{16\sigma_P^2 - \sigma_{\bar{P}}^2}{15\sigma_P^2}. $$  \hspace{1cm} (2)

$\Omega_P$ measures the degree to which the sixteen precipitation time series generated by the ensemble members are similar. In essence, $\Omega_P$ is equivalent to the ratio of explained precipitation variance to total precipitation variance; it varies from (approximately) 0 to 1, with higher values implying a greater contribution of boundary and initial conditions (and thus a lesser contribution of atmospheric chaos) to the evolution of precipitation in a given AGCM. Notice that if all simulations produced precisely the same precipitation time series, implying no chaotic contribution, $\sigma_{\bar{P}}$ would be identical to $\sigma_P$, and $\Omega_P$
would be exactly one. K02 provides a graphic interpretation of the meaning of the $\Omega_P$ diagnostic (see Figure 2 of K02).

Figure 2 of the present paper shows the global fields of $\Omega_P(W)$ (that is, $\Omega$ from the W ensemble) for all 12 AGCM-LSM combinations. Land states are not prescribed in ensemble W; thus, $\Omega_P(W)$ reflects the extent to which low frequency seasonal variations, as induced by the time variations of imposed boundary conditions and forcing alone (e.g., SST, vegetation structure, and solar declination), lead to strong coherence in the precipitation rates. (Note that while this coherence may be strengthened in ensemble W through land-atmosphere feedback, the ultimate source of the coherence lies in the prescribed boundary conditions and forcing.) The high values of $\Omega_P(W)$ tend to be clustered in the tropics (where the ITCZ is migrating) and in a few midlatitude regions, such as eastern and southern Europe. An example of a model's behavior at a grid cell with high $\Omega_P(W)$ is shown in Figure 3. Plotted in the figure are sixteen time series of precipitation, one for each of the ensemble W simulations produced by CCSR/NIES over a grid cell in equatorial Africa. The same strong seasonality pervades each ensemble member, leading to a high synoptic-scale precipitation coherence over the duration of the simulation and thus to a high value (0.59) of $\Omega_P(W)$.

To quantify land-atmosphere coupling strength, we note that in ensemble R, the explained variance – the coherence of precipitation between the ensemble members – has two distinct sources: (a) the prescribed land vari-
ables and (b) the background seasonal behavior that contributes to \( \Omega_P(W) \), as exemplified in Figure 3. Thus, subtracting \( \Omega_P \) for ensemble \( W \) from that for ensemble \( R \) should isolate the impact of prescribed land variables on the synoptic-scale precipitation variance. We use the difference in coherence \( \Omega_P(R) - \Omega_P(W) \) to measure land-atmosphere coupling strength associated with the prescription of all land variables. At a single grid cell, an \( \Omega \) difference of 0.06 is significant at the 95% confidence level.

Of course, if \( \Omega_P(W) \) is already close to 1, the impact of land conditions will necessarily be small. This is not a major issue, however; the maximum of \( \Omega_P(W) \) across the different models over non-ice land points lies below 0.8, and \( \Omega_P(W) \) generally falls far below this maximum. For some models (GFS, BMRC), \( \Omega_P(W) \) values are small across the globe, implying that their "background" low frequency precipitation variations are quite small, at least for the 92-day period considered.

Figure 4 shows the global fields of \( \Omega_P(R) - \Omega_P(W) \) for all 12 AGCM-LSM combinations. This figure is, in effect, a more comprehensive version of Figure 3 in K02. As in that earlier figure, Figure 4 shows a wide intermodel disparity in the degree to which the atmosphere responds to the imposed land surface anomalies. Some models have relatively high values of \( \Omega_P(R) - \Omega_P(W) \) (e.g., GFDL, NSIPP, CAM3, COLA, CSIRO), and others show relatively low values (e.g., HadAM3, BMRC, GFS, GEOS-CRB). Generally, however, \( \Omega_P(R) - \Omega_P(W) \) is small in southern hemisphere mid-
latitudes and in deserts, presumably because the low mean evaporation rates imply little variability in the surface energy balance. The low evaporation rates in the summer hemisphere presumably reflect wintertime conditions; a repeat of the experiments for austral summer could prove useful.

While the patterns and magnitudes shown in Figure 4 are intriguing, they may be of largely academic interest, since they may be controlled mostly by “fast” land surface prognostic variables — variables having little temporal memory and which cannot be used for prediction. In contrast, ensemble S focuses on the “slow” subsurface moisture variables that can contribute to prediction. Figure 5 shows the global fields of $\Omega_P(S) - \Omega_P(W)$ for all 12 AGCM-LSM combinations. In analogy to $\Omega_P(R) - \Omega_P(W)$, $\Omega_P(S) - \Omega_P(W)$ isolates the contribution of prescribed subsurface soil moisture to precipitation variability — to the evolution of precipitation on synoptic timescales.

As in the comparisons of $\Omega_P(R) - \Omega_P(W)$, a strong diversity of coupling strength is seen amongst the AGCMs. Some models (e.g., GFDL, CAM3, NSIPP, CCCma) have a distinct “blocky” structure associated with their $\Omega_P(S) - \Omega_P(W)$ values — large patches of relatively high $\Omega_P(S) - \Omega_P(W)$ can be seen, for example, in central North America and the Sahel. Other models (e.g., CCSR/NIES, HadAM3, BMRC, GFS) have relatively few such structures; for the most part, small values of $\Omega_P(S) - \Omega_P(W)$ are scattered randomly across the globe. Note that a certain amount of agreement is seen in the positioning of the $\Omega_P(S) - \Omega_P(W)$ structures that do appear. This
will be discussed further in section 5.

Most models even show some negative values of $\Omega_P(S) - \Omega_P(W)$. The reasons are unclear, but the highly infrequent negative values may have occurred by chance—according to monte carlo analysis, under an assumption of independent rainfall amounts in consecutive 6-day periods, a difference of either -0.1 or 0.1 is statistically significant at the 99.6% level, so a false negative may occur in about 0.4% of the grid cells plotted. Differences of -0.05 and 0.05 are statistically significant at the 92% level. (Relaxing the assumption of independence makes the occurrence of spurious negative values slightly more likely.) Note that for the $\Omega_P(R) - \Omega_P(W)$ field, negative values may have a different source; the specification of land states may have led to artificially large vertical gradients between the land surface and the free-running atmosphere, causing instabilities and unrealistic fluxes in the integrations and thus abnormal model behavior (Reale et al. 2002).

For ease of comparison, Figure 6 shows the values of $\Omega_P(W)$, $\Omega_P(R) - \Omega_P(W)$ and $\Omega_P(S) - \Omega_P(W)$ for each model, averaged across all non-ice land points. Note the different scale for the bottom plot; the specification of subsurface soil moisture has a much smaller impact on precipitation's synoptic-scale variability than does either the background seasonality (top plot) or the specification of “fast” variables (middle plot). Though the numbers for $\Omega_P(S) - \Omega_P(W)$ appear small, we must keep in mind that the global averaging will hide any reasonably large $\Omega_P(S) - \Omega_P(W)$ values that appear
regionally. In certain regions, subsurface soil moisture can have a significant impact on rainfall – and can thus be useful for seasonal prediction – even if the globally averaged impact appears small.

The model diversity seen in the histograms reflects that seen in the maps. On a global average basis, the coupling strength associated with all land reservoirs (middle plot of Figure 6, showing $\Omega_P(R) - \Omega_P(W)$) is more than four times higher in some models (e.g., CAM3, NSIPP) than it is in some other models (e.g., BMRC, HadAM3, GEOS-CRB). The impact of subsurface soil moisture on the evolution of precipitation (bottom plot) is just as model-dependent; the more strongly coupled models (GFDL, CAM3, NSIPP, CCCma) stand out distinctly from the more weakly coupled models (HadAM3, BMRC, GFS).

4.2 Surface Air Temperature

The global fields of the $\Omega$ difference for surface air temperature are presented in Figure 7. The temperature analysis focuses on ensemble S, since temperatures in ensemble R are overly influenced by the specified ground temperatures. In analogy to the precipitation analysis, the global fields of $\Omega_T(S) - \Omega_T(W)$ indicate a strong disparity in the control of subsurface soil moisture on the synoptic-scale variability of air temperature, with some models (e.g., GFDL, HadAM3, CCCma, CSIRO) showing a high degree of control and others (e.g., COLA, BMRC, GFS, CCSR/NIES) showing a much more limited control. Also in analogy to the precipitation analysis, some regions
of coupling (e.g., the Sahel, northeastern China, and south-central North America) tend to show up in many of the models.

The top panel of Figure 8 shows the global average (over non-ice land points) of $\Omega_T(W)$. The averages are much larger than those for $\Omega_P(W)$, presumably because of the strong background seasonal temperature cycle within each model. The middle panel of Figure 8 shows the average of $\Omega_T(S) - \Omega_T(W)$ across non-ice land squares for each model. Comparing this figure with the bottom panel of Figure 6 reveals two important things. First and foremost, the land's control on air temperature is generally much larger than its control over precipitation. This is not surprising given that evaporation, through latent cooling and the associated impact on sensible heat flux, has a stronger connection to near-surface temperature than to precipitation, which is produced at higher atmospheric levels and thus depends in part on convection and boundary layer formulations. (This is addressed in more detail in the companion paper [Guo et al., this issue].) Second, a low control on precipitation relative to other models does not imply a relatively low control on air temperature as well. HadAM3, for example, has a reasonably high average $\Omega_T(S) - \Omega_T(W)$ values despite its low average value of $\Omega_P(S) - \Omega_P(W)$. 
5 "Hot Spots" of Land-Atmosphere Coupling

Figure 5 does suggest some similarity between models in precipitation’s response to soil moisture, at least in terms of geographical distribution. Several models, for example, place relatively high values of $\Omega_P(S) - \Omega_P(W)$ in the Sahel and in central North America. Some intermodel similarity is also seen in the $\Omega_T(S) - \Omega_T(W)$ fields. The GLACE experiment has a noteworthy strength: it provides a unique chance to quantify multi-model “agreement” in the locations of land moisture impact on the atmosphere. It can provide a more robust estimate of where the coupling is relatively strong, an estimate that is less subject to the quirks or deficiencies of any one particular model.

This strength of GLACE motivated a recent paper (Koster et al., 2004) highlighting these “hot spots” for precipitation, i.e., identifying the areas which, for many of the models, the land-atmosphere coupling strength is relatively large. Plotted in that paper was the global field of $\Omega_P(S) - \Omega_P(W)$, averaged across all participating models. A slightly different version of the plot is shown in the top panel of Figure 9; the version is different because here, to maintain consistency with the rest of our 2-part paper, statistics are computed on the precipitation values themselves rather than on their natural logarithms. (Although performing statistics on the natural logarithms of precipitation is a common and useful practice in hydrology and meteorology, since it reduces noise associated with high rainfall amounts, it produces technical problems for some of our analyses.) To produce the plot, the results
from each model were disaggregated to the same very fine grid, one with a resolution of $0.5^\circ \times 0.5^\circ$. Disaggregation was performed in the simplest way possible. Each $0.5^\circ \times 0.5^\circ$ grid cell lies wholly or mostly within a coarse grid cell of a given model. The precipitation rate assigned to the fine grid cell was that which applies to the coarse grid cell containing it.

The top panel of Figure 9 shows that hot spots appear in the central Great Plains of North America, northern India, the Sahel, equatorial Africa, and a few additional regions. Because the logarithms of rainfall amounts are not used, however, the magnitudes of the plotted coupling strengths are slightly reduced relative to those in Koster et al. (2004).

Note that a strict arithmetical average across the twelve models was used to generate the figure. An alternative approach would be to give added weight to the models with more realistic climate. The bottom panel of the figure shows the results of one such weighted calculation. In the approach used here, the $\Omega_P(S) - \Omega_P(W)$ values are averaged across only the eight models that, at a given grid cell, best reproduce the observed climatological average precipitation for June through August (from GPCP [Huffmann et al, 1997]). Thus, a different set of eight models may contribute to the plotted average at adjacent locations. This approach is limited in scope; indeed, all possible weighting approaches are necessarily imperfect. The two chief deficiencies of the weighting applied here are that (i) rainfall rates used to evaluate the "realism" of a model may reflect the year chosen for the SST boundary
condition, whereas the climatological average for observations represents a mean over many years, and (ii) a model may have a realistic mean climatology but poor variability characteristics, and vice-versa. Nevertheless, the results of the exercise are illuminating. While the positions of the hot spots are similar to those in the top panel, the magnitudes of the averages have, in general, increased. In other words, by focusing on the models that appear to be more realistic in terms of precipitation climatology, we have increased the derived average coupling strength.

The equivalent two maps for air temperature are plotted in Figure 10. The top panel shows $\Omega_T(S) - \Omega_T(W)$ averaged over all the models, and the bottom panel shows the “weighted average” result, again an eight-model average based on the realism of simulated precipitation. The results from both maps suggest strong synoptic-scale coupling for temperature in the Sahel, the central Great Plains of North America, India, and (in contrast to precipitation) eastern Asia. Notice that the average coupling strength is significantly larger than that for precipitation.

Again, direct estimates of coupling strength from observations do not exist, and the coupling results from any one model may simply reflect the peculiarities of that model. The multi-model averaging procedure, though subject to deficiencies shared by multiple models, and though unable to generate quantitative estimates of reliability, still provides what is probably the best estimate possible for land-atmosphere coupling strength in the real world.
6 Summary

In nature, rainfall certainly affects soil moisture, and soil moisture may affect rainfall. As part of the GLACE project, a number of AGCM groups have performed a numerical experiment designed to isolate the latter direction of causality. Through GLACE, we quantify the impact of land conditions on the evolution of precipitation and temperature in boreal summer in each of the models, and we compare in detail the differences in this “coupling strength” between the models.

This paper has two main functions: (i) it describes the GLACE experiment with enough detail to allow its execution in the future by any modeling group, and (ii) it documents the range of coupling strengths implicit now in the participating models, so that any future group can put their results immediately into context. The range of coupling strengths uncovered by GLACE is indeed large, as indicated by Figures 4 through 8. We emphasize again that this intermodel disparity is not a trivial result, since coupling strength is not an explicitly defined quantity in the AGCMs – it is rather a complex product of many interacting model parameterizations. Most modelers have little notion of the degree of land-atmosphere coupling implicit in their models. The GLACE experiment provides, for the first time, an established methodology for its computation. Being able to compare a given model’s coupling strength to that of other models is critical for interpreting, for example, land use impact experiments or precipitation forecasts based on
soil water initialization.

A side benefit of the GLACE experiments is the determination of multi-model "hot spots" of land-atmosphere coupling – regions that, according to several AGCMs, have a relatively high coupling strength. Figure 9 shows, for example, that the Sahel and the Great Plains of the U.S. are hot spots of coupling for precipitation at synoptic timescales. The multi-model nature of this result gives it added validity; either several models are wrong in a similar way, or these are indeed regions of strong coupling in the real world.

Two questions naturally arise from this study. First, what causes the geographical variations in coupling strength seen for a given model in Figures 5 and 7? Second, what causes the model-to-model differences in coupling strength, as summarized by the histogram plots? The answers certainly relate to differences in the parameterizations employed by the models and to differences in the simulated climates – some hydroclimatological regimes are presumably more amenable to coupling than others. Part 2 of this series of papers (Guo et al., this issue) addresses these two questions in detail.

Appendix A: Details of Experimental design

A.1 Model-Specific Aspects of Experiment
The spatial resolution and the time step used necessarily varies amongst the participating AGCMs. Each group used a resolution typical for their model. Each group also applied their own strategy for writing out the prognostic variables in Ensemble W and for reading them in Ensembles R and S.

A.2 Initialization of Ensemble Members

The members of an AGCM ensemble typically differ only in their initial atmospheric and land surface conditions. The approach for assigning the initial conditions is not strictly specified by GLACE; the only requirement is that the initial conditions be fully consistent with the AGCM being used. They are not allowed to be imported from some other model.

Several approaches for initializing land and atmosphere states are possible; they are listed in order of preference below. (That is, approach (a) is preferred most.) The key is to produce sets of initial conditions that sample the full range of possible land and atmosphere states. Initial land conditions between ensemble members, for example, should not be allowed to be artificially similar, as can happen through the commonly used approach (e).

(a) Some groups have available an archived series of 16 or more parallel multidecade AMIP-type simulations (i.e., simulations using SSTs prescribed from observations) from which to extract 16 different
sets of land and atmosphere states for June 1, 1994. These states can be used to initialize the W, R, and S ensembles. If daily data from the 16+ parallel AMIP-type simulations are archived, then in effect ensemble W is already almost finished; only one more simulation – the one that writes the time step information to W1STATES – needs to be performed for that ensemble.

(b) If the number of archived multidecade AMIP-type simulations is less than 16 but greater than 1, they can still be used, as long as the years from which the June 1 land and atmosphere states are extracted belong to the set of “quiescent” years (i.e., years with little El Niño or La Niña signal). For the purposes of this experiment, these years are 1951, 1952, 1959, 1960, 1961, 1963, 1977, 1979, 1980, 1981, 1986, 1990, and 1994, years for which the Niño3 anomaly has an absolute value less than 0.5 for the three months preceding the initialization date. A group, for example, may have four archived parallel AMIP simulations. Extracting restart files for June 1 of 1977, 1979, 1990, and 1994 from each of the 4 simulations would give a total of 16 sets of initial states for the experiment.

(c) A more tractable approach for many groups is to access restart files (initial conditions) from a preexisting single 16+ year simulation.
In particular, if such a simulation exists in which SSTs do not vary from year to year (i.e., they are set to seasonally-varying climatological values), then the land and atmosphere states produced on 1 June in each of 16 years of the simulation can be used to initialize the 16 ensemble members.

(d) If the only 16+ year simulation available is an AMIP-type simulation (one with interannually-varying SSTs), then the June 1 conditions determined for the different years in this simulation can be used to initialize the June-August 1994 simulations. With this approach (as with approach (b)), the calendar years for the AMIP simulation are forced to lose their meaning. For example, suppose the restart files produced by an AMIP-type simulation covering 1979-1994 are available. The 1 June 1979 atmosphere and land states can be used to initialize one member of ensemble W (and of ensembles R and S), the 1 June 1980 states can be used to initialize another ensemble member, and so on.

(e) A common approach to assigning initial conditions to the different members of an ensemble is to run the AGCM for, say, 16 June days and write out the atmosphere and land states at the beginning of each day. Each daily set of fields would then be used as initial
conditions. This type of approach, however, is highly undesirable for the present experiment, since the land surface states would not have time to vary much during the short simulation – the initial land conditions amongst the different members of ensemble W would not represent the broad range of states the model is capable of achieving.

Note that given the design of the experiments, the initialization of all land states for ensemble R and the deeper soil moisture states for ensemble S is actually irrelevant. Note also that in all cases, the atmosphere may feel a "shock" at the beginning of the R and S simulations, since initially it will not be in equilibrium with the prescribed surface state. K02 examined the effect of this shock on $\Omega_P$ and concluded that it was small. Nevertheless, the first 8 days or so of each 3-month simulation is excluded from the data analyses, to avoid its effects.

A.3 Energy and Water Balance Considerations

The design of ensembles R and S necessarily precludes the maintenance of a strict energy and water budget below the land-atmosphere interface. Note, however, that energy and water in the atmosphere and across the interface are still perfectly conserved; conservation of energy and water is only "neglected" within the land reservoirs themselves. Since these special-
ized experiments focus solely on the atmospheric response to land conditions through the interface, the lack of conservation below the interface is deemed acceptable.

A.4 Redundancy of Simulations

If the initial conditions used by simulation W1 (the simulation that wrote out its state variables into file W1.STATES) are also used to initialize one of the members of ensemble R (say, simulation “R1”), then by the construct of the experiment, the weather (and thus the precipitation) generated in simulations W1 and R1 should be identical. The same holds true if W1’s initial conditions are used to initialize a member of ensemble S. Modeling groups can, if they wish, take advantage of this redundancy by using simulation W1 as a member of both the R and S ensembles. In other words, in reality only 15 new simulations need to be performed for both the R and S ensembles. (Note that truncation errors may, in fact, allow simulation R1 or S1 to diverge from simulation W1. These truncation effects are irrelevant; the point is that simulation W1 can properly serve as a member of both the R and S ensembles.)

Acknowledgments. GLACE is a joint project of the Global Energy and Wa-
ter Cycle Experiment (GEWEX) Global Land Atmosphere System Study (GLASS) panel and the Climate Variability Experiment (CLIVAR) Working Group on Seasonal-to-Interannual Prediction (WGSIP), all under the auspices of the World Climate Research Programme (WCRP). The processing of the multi-model results was supported by National Aeronautics and Space Administration grant NAG5-11579. The individual contributions were supported by the participants’ home institutions and funding agencies.

Popular Summary:

A wetter-than-usual soil may lead to higher-than-usual evaporation, which in turn may lead to increased precipitation. This soil moisture - precipitation connection, if verified and properly utilized, would contribute significantly to seasonal forecasting efforts. Seasonal forecasters could then take advantage of the fact that initialized soil moisture anomalies can persist for months.

The problem with verifying the soil moisture - precipitation connection with observational data is that the required data on the large scale do not exist and are logistically impossible to obtain. Climatologists have thus relied instead on modeling studies to quantify the connection. These modeling studies have their own limitations, however; most notably, the results can be strongly model dependent.

To forward our understanding of the soil moisture - precipitation connection, and in particular to address the question of model dependence in published results, the authors have operated GLACE, an international intercomparison project designed to quantify the strength of the soil moisture - precipitation connection (the "coupling strength") across a broad range of atmospheric general circulation models. Through GLACE, we find that the different models do indeed show a broad disparity in coupling strength distribution. GLACE, however, also provides an intriguing result. Despite the intermodel disparity, certain areas of the Earth show a large coupling strength in many models, suggesting that the existence of significant coupling strength in these areas is not so model-dependent. Given the lack of observational data, such a multi-model determination of areas with strong coupling strength is arguably the best estimate of such areas attainable by any method.

Part 1 of the paper has two key goals: to document the intermodel variability in coupling strength existing in models today, and to provide a full set of instructions for repeating the experiment, so that other groups can test their models and compare their results directly with those documented in the paper. Part 2 (with Z. Guo as lead author) delves into the "whys" of the intermodel disparity, explaining in general terms what controls the coupling strengths of the different models. Together, the papers document the key results of a scientifically productive project.
