Data-Rate Estimation for Autonomous Receiver Operation

A. Tkacenko\textsuperscript{1} and M. K. Simon\textsuperscript{1}

In this article, we present a series of algorithms for estimating the data rate of a signal whose admissible data rates are integer base, integer powered multiples of a known basic data rate. These algorithms can be applied to the Electra radio currently used in the Deep Space Network (DSN), which employs data rates having the above relationship. The estimation is carried out in an autonomous setting in which very little a priori information is assumed. It is done by exploiting an elegant property of the split symbol moments estimator (SSME), which is traditionally used to estimate the signal-to-noise ratio (SNR) of the received signal. By quantizing the assumed symbol-timing error or jitter, we present an all-digital implementation of the SSME which can be used to jointly estimate the data rate, SNR, and jitter. Simulation results presented show that these joint estimation algorithms perform well, even in the low SNR regions typically encountered in the DSN.

I. Introduction

In an autonomous radio operation setting, one of the first parameters that we would like to estimate reliably would be the data rate of the received signal. Knowledge of this parameter is required to carry out maximum-likelihood (ML) detection [1] of other parameters such as the carrier phase or modulation type. Though ML estimation of the data rate itself is statistically optimal, given that there is little to no a priori knowledge of the incoming signal, this approach is often difficult if not impossible to do in practice.

One mitigating factor for the autonomous radio under consideration is the fact that the data rates are assumed to come from a set of known values, such as the data rates used in the Electra radio [2]. In particular, the data rates here are assumed to be related by integer powers of an integer base $B$. This assumption, as will soon be shown, allows us to estimate the true data rate based on estimates of the signal-to-noise ratio (SNR) computed for various assumed data rates. The method for estimating the SNR here is the split-symbol moments estimator (SSME) discussed in [3]. This estimator is appealing in that the only parameter required for its operation is the assumed data rate. Hence, estimation of the data rate can be done jointly with that of the SNR.

\textsuperscript{1}Communications Architectures and Research Section.

The research described in this publication was carried out by the Jet Propulsion Laboratory, California Institute of Technology, under a contract with the National Aeronautics and Space Administration.
Though this approach provides us with a way to estimate both the data rate and SNR together, it will be shown that it is sensitive to symbol-timing error or jitter. In fact, the presence of symbol-timing error can severely degrade the performance of this estimator. To overcome this, a modification is proposed in which the jitter is quantized and estimated alongside the data rate and SNR. This approach, based on a so-called generalized likelihood ratio test (GLRT) [4], is robust in the presence of symbol-timing error and can be used to jointly estimate the data rate, SNR, and symbol-timing error all at once. The estimates of the symbol-timing error obtained can then be used as coarse initial estimates for the data transition tracking loop (DTTL) [5], which can be used later in the receiver to obtain a fine estimate of the timing jitter.

A. Outline

In Section II, we review the received signal model assumptions and show how the SSME can be used to obtain an estimate of the data rate in the absence of symbol-timing error. This leads to an algorithm for estimating the data rate, which we present in Section II.C. A slight modification to this algorithm which resembles a GLRT-type approach is presented in Section II.D.

In Section III, we investigate the effects of the presence of symbol-timing error on the data-rate estimation algorithm. There, it is shown that the presence of a severe jitter can in fact cause the data-rate estimator to unequivocally fail.

By quantizing the symbol-timing error, we show in Section IV how to modify the algorithms in Sections II.C and II.D to account for the presence of symbol-timing error. There, an all-digital implementation of the SSME-based data-rate estimation system is presented in Section IV.A. This leads to a joint data rate/SNR/symbol-timing error estimation technique which we describe in Section IV.B and a GLRT-type modification to this method described in Section IV.C.

Simulation results for the joint data rate/SNR/symbol-timing error estimation techniques of Sections IV.B and IV.C are presented in Section V. There, the strengths and weaknesses of each of the proposed techniques are revealed in terms of probability of data-rate misclassification, SNR estimation error, and jitter estimation error.

Concluding remarks are made in Section VI. There we discuss the ramifications of the proposed algorithms on the estimation of other parameters of the received signal. In particular, we focus on how the algorithms can be used to provide side information for estimating these parameters.

II. Data-Rate Estimation Based on the Mean of the SSME SNR Estimator

A. Signal Model and Assumptions

The baseband signal received at the autonomous radio is assumed to consist of a constant amplitude digital data stream corrupted only by artifacts due to the conversion from IF to baseband as well as additive noise. Mathematically, the received signal $y(t)$ is assumed to have the following form:

$$y(t) = A \left( \sum_{k=-\infty}^{\infty} d_k p(t - (k + \epsilon)T) \right) e^{j(\omega_c t + \theta_c)} + n(t)$$

(1)
Here, we have the following:

\[ A = \text{signal amplitude} \]
\[ d_k = k\text{th data symbol (typically assumed to be an } M\text{-PSK symbol [1]} \]
\[ p(t) = \text{data pulse shape (typically either a non-return-to-zero (NRZ) or a Manchester pulse [1]} \]
\[ T = \text{symbol period of the data} \]
\[ \epsilon = \text{symbol-timing error (jitter) (assumed to be uniform over the interval [0, 1)} \]
\[ \omega_r = \text{residual frequency offset after demodulation} \]
\[ \theta_c = \text{carrier phase (assumed to be uniform over the interval [0, } 2\pi) \]
\[ n(t) = \text{complex additive white Gaussian noise (AWGN) [1] whose real and imaginary parts are} \]
\[ \text{uncorrelated, zero mean processes with power spectral density (psd) } N_0/2 \]

Prior to estimating parameters such as the carrier phase \( \theta_c \) or the frequency offset \( \omega_r \), we would like to estimate the data rate given by \( R \triangleq 1/T \). As with the Electra radio [2], we assume that the set of possible data rates \( \{R\} \) comes from a known finite set of values of the form

\[ R = B^\ell R_b, \quad 0 \leq \ell \leq \ell_{\max} \quad (2) \]

where \( B, \ell, \) and \( \ell_{\max} \) are nonnegative integers and \( R_b \triangleq 1/T_b \) is the basic (or lowest) data rate. In other words, every possible data rate is a base power of the lowest basic rate. Here \( B \) is called the rate base, whereas \( \ell \) is referred to as the rate power. We denote the maximum rate power by \( \ell_{\max} \) and so the number of possible data rates is given by \( (\ell_{\max} + 1) \) as can be seen from Eq. (2). For the Electra radio, we have [2],

- \( B = 2 \)
- \( \ell_{\max} = 12 \)
- \( R_b = 1 \text{ ksymbol/s} \)

With regard to estimating the data rate of the signal \( y(t) \) from Eq. (1), it is assumed that we know both the rate base \( B \) as well as the basic data rate \( R_b \). Hence, from Eq. (2), the only ambiguity of the data rate that exists is the rate power \( \ell \). This greatly simplifies the data-rate estimation problem, since \( \ell \) only varies over a finite set of known integers. In what follows, we will assume that the symbol-timing error \( \epsilon \) is zero. The case for which \( \epsilon \neq 0 \) will be considered in Section III.

**B. Relation of the SSME SNR Estimator to Data-Rate Estimation**

A block diagram of the SSME system for estimating the SNR of the signal \( y(t) \) from Eq. (1) is shown in Fig. 1 for the case of a rectangular NRZ pulse shape. (For different pulse shapes, the only thing that needs to be changed is that the half-symbol integrate and dump (I&D) circuits need to be replaced with half-symbol matched filters.) Here, \( T_s \) denotes the assumed symbol period of the system, \( N_s \) denotes the number of system observations, and \( \omega_{xy}, \hat{h}^+, \) and \( \hat{h}^- \) denote frequency and phase compensation factors as described in [3].
From [3], it is known that if the system data rate $R_s \triangleq 1/T_s$ and $N_s$ satisfy

$$R_s = LR, \quad N_s = LN$$

for some positive integers $L$ and $N$, then the mean of the SNR estimate $\hat{R}_l$ is given as follows:

$$E[\hat{R}_l] = \frac{R N + 1}{LN - 1} = \frac{\frac{R}{L} + \frac{1}{LN}}{1 - \frac{1}{LN}} = \frac{R}{L} + \frac{1}{LN} \left( \frac{R}{L} + 1 \right) + O \left( \frac{1}{N^2} \right)$$

where $R$ is the true SNR given by $R = A^2 T/N_0$. For large $N$, this simplifies within $O(1/N)$ to become

$$E[\hat{R}_l] \approx \frac{R}{L} \quad (3)$$

In other words, if the assumed data rate $R_s$ is an integer multiple $L$ of the true data rate $R$, then the SSME still works as before, but formulates an estimate of the reduced SNR $R/L$, when the number of observations is large enough. As we shall soon see, it is this property that will allow us to use the SSME system to estimate the data rate.

To see how the SSME can be used to estimate the data rate, suppose first that the SSME operates at the highest possible rate, which is simply $R_s = B^{\ell_{\text{max}}} R_b$ from Eq. (2). As $R = B^{\ell} R_b$, we have $R_s = LR$ where $L = B^{\ell_{\text{max}} - \ell}$. Then, from Eq. (3), we have,

$$E[\hat{R}_0] = \frac{R}{B^{\ell_{\text{max}} - \ell}}$$
If the SSME is operated at the next lower rate (i.e., $R_s = B\ell_{\text{max}} - 1R_b$), then we have $L = B\ell_{\text{max}} - \ell - 1$ and so from Eq. (3), we have

$$E\left[\hat{R}_1\right] = \frac{R}{B\ell_{\text{max}} - \ell - 1} = BE\left[\hat{R}_0\right]$$

In other words, lowering the rate by one step increases the mean of the SNR estimate by a factor of $B$.

If we continue to run the SSME, lowering the assumed data rate $R_s$ by a factor of $B$ at each run, then on the $(\ell_{\text{max}} - \ell)$th run, we will obtain an SNR estimate based on the true data rate $R$, in which case we have

$$E\left[\hat{R}_{\ell_{\text{max}} - \ell}\right] = R = B\ell_{\text{max}} - \ell E\left[\hat{R}_0\right]$$

Note that, up to this point, we have

$$E\left[\hat{R}_i\right] = B^iE\left[\hat{R}_0\right] \quad (4)$$

In other words, the mean of the SNR estimate monotonically increases by a factor of $B$ each time the rate is lowered until the true data rate (and hence the true SNR) is reached.

If the assumed data rate is lowered one more step so that $R_s = B\ell - 1R_b = R/B$, then the SSME will attempt to create an SNR estimate based on $B$ successive data symbols. This will severely degrade the performance of the estimator since the data symbols fluctuate randomly. To see this, consider the case where $B = 2$ and the data come from a binary phase-shift keying (BPSK) constellation [1]. In this case, the signal portion of the I&D outputs $y_{0,k}$ and $y_{1,k}$ can either constructively or destructively interfere depending on whether adjacent data symbols are the same or different, respectively. This is illustrated in Fig. 2.

When two adjacent data symbols are the same, as in Fig. 2(a), we will get a valid contribution to the SNR estimate, since $\left|u_k^+\right|^2$ from Fig. 1 will be an approximate measure of the signal power plus the noise power, whereas $\left|u_k^-\right|^2$ will be a measure of the noise power. However, when two adjacent data symbols are different as in Fig. 2(b), the opposite scenario takes place, i.e., $\left|u_k^+\right|^2$ becomes a measure of the noise power whereas $\left|u_k^-\right|^2$ becomes a measure of the signal-plus-noise power. This will result in a severely degraded estimate of the SNR since half of the time adjacent data symbols will be the same and half of the time they will be different. (The reason for this is that the data sequence is assumed to come from an independent, identically distributed (i.i.d.) source [1].) This degradation may even lead to negative estimates of the SNR which are clearly absurd.

For the purpose of data-rate estimation, this degradation can be used to indicate that the assumed data rate of the SSME system was lowered excessively by one step. The elegance of this method of estimating the data rate is the rapid degradation that is expected once the assumed data rate has been lowered beyond the true data rate. Recall from Eq. (4) that up until the true data rate is reached, the mean of the SNR estimate will increase by a factor of $B$ until the true SNR is reached. Once the assumed
data rate is lowered by one more step, however, the mean of the SNR estimate will decrease significantly. Hence, the SSME provides us with a way to estimate the data rate via a sharp transition in the estimate of the SNR.

An algorithm to estimate the data rate based on this phenomenon is presented below.

C. SSME Data-Rate Estimation Algorithm

(1) Assume that the data rate is the maximum rate, i.e., set $R_s = B^{\ell_{\text{max}}} R_b$. Run the SSME and compute an estimate of the mean of the SNR and call it $\hat{\mu}_{R_0}$. Set $i = 1$.

(2) Lower the SSME data rate by a factor of $B$, i.e., set $R_{\text{new}} = R_{\text{old}} / B$. Compute an estimate of the SNR mean and call it $\hat{\mu}_{R_i}$.

(3) If $\hat{\mu}_{R_i} \geq \hat{\mu}_{R_{i-1}}$, then increment $i$ by 1 and go to Step (2). Otherwise stop and estimate the SNR to be $\hat{\mu}_R = \hat{\mu}_{R_{i-1}}$ and the data rate to be $\hat{R} = B^{\ell_{\text{max}}-(i-1)} R_b$.

In practice, the estimate of the SNR mean $\hat{\mu}_{R_i}$ is computed as an ensemble average of observed SNR estimates $\hat{R}_i$ calculated over several blocks of the received signal. If a large enough ensemble of blocks is used, then we will have $\hat{\mu}_{R_i} \approx E\left[\hat{R}_i\right]$ as desired.

It should be noted that this algorithm terminates as soon as $\hat{\mu}_{R_i} < \hat{\mu}_{R_{i-1}}$. In other words, the assumed data rate of the SSME is lowered only until the condition $\hat{\mu}_{R_i} \geq \hat{\mu}_{R_{i-1}}$ is not satisfied. Although this approach works in theory assuming that the number of observations is large enough, in practice this can often lead to a premature termination of the algorithm depending on the value of the variance of the SSME SNR estimate. (See [3] for more details.) For cases where the SNR is low, such as in the Deep Space Network (DSN), this can lead to a perturbation in the calculation of the mean of the SNR such that the condition $\hat{\mu}_{R_i} < \hat{\mu}_{R_{i-1}}$ will occur before it should, causing the algorithm to halt prematurely.

Since we expect the largest SNR to occur when the assumed data rate is equal to the true data rate, one alternative to this algorithm is to run the SSME for all data rates and estimate the data rate as the one yielding the largest SNR mean. This forms the basis for the GLRT-type data-rate estimation algorithm presented below.
D. GLRT-Type SSME Data-Rate Estimation Algorithm

(1) Run the SSME for all data rates and (as before) let \( \hat{\mu}_{R_i} \) denote the estimate of the mean of the SNR for the \( i \)th largest data rate.

(2) Define the optimal index \( i_{\text{opt}} \) to be \( i_{\text{opt}} = \arg \max_{0 \leq i \leq \ell_{\text{max}}} \hat{\mu}_{R_i} \). Then, estimate the true SNR and data rate as follows:

\[
\hat{\mu}_{R} = \hat{\mu}_{R_{i_{\text{opt}}}} \\
\hat{R} = B^{\ell_{\text{max}} - i_{\text{opt}}} R_b
\]

For a traditional GLRT estimator, the conditional-likelihood function (CLF) [4] of the observables is maximized over the unknown parameters, as opposed to being averaged over them as is done in ML estimation. In that sense, this algorithm is a GLRT-like approach in that the SNR is chosen to be the maximum value obtained over the unknown parameter of the data rate. The data rate, in turn, is estimated as the rate which yields the largest SNR mean.

As will be shown in Section V through simulations, the GLRT-type data-rate estimation algorithm outperforms the algorithm of Section II.C for low SNR when the true data rate is the lowest data rate. The reason for this is that this algorithm calculates an estimate of the SNR for all rates and doesn’t prematurely terminate as the previous algorithm may do.

Prior to showing simulation results for these algorithms, we first investigate the effects of the presence of symbol-timing error on estimating the data rate. There, we show that these effects can seriously adversely affect the performance of the above proposed data-rate estimation algorithms. In Sections IV.B and IV.C, we present modifications to the algorithms of Sections II.C and II.D, respectively, which account for the presence of symbol-timing error.

III. Effects of Symbol-Timing Error on Estimating the Data Rate

In the previous section, we assumed that the symbol-timing error or jitter \( \epsilon \) was zero. From [3], it is known that the presence of jitter will have the effect of degrading the estimate of the SNR of the SSME. Heuristically speaking, the reason for this is that the half-symbol I&D outputs will contain the contributions of two adjacent data symbols. As the data symbols are i.i.d., the signal components of the I&D outputs will be degraded similarly to the way in which they were degraded in Section II.B when the assumed data rate was lower than the true data rate. This effect becomes more pronounced as \( \epsilon \) reaches its worst case value of \( 1/2 \).

To mitigate the effects of the presence of a nonzero \( \epsilon \), the approach suggested in [3] was to increase the data rate of the SSME system by a factor of \( L \). By doing so, the vast majority of the half-symbol I&D outputs contain contributions due to only one data symbol as desired. The effects due to those containing contributions from two adjacent data symbols becomes negligible and so the oversampled estimator is then robust to the presence of jitter.

This principle of oversampling is used in the data-rate estimation algorithms of Section II. There, the oversampling factor is reduced at each stage until the largest SNR mean is obtained. The problem with these algorithms in the presence of symbol-timing error is that the SNR will appear to be degraded once the assumed data rate is lowered to the true data rate and not afterwards. In other words, for nonnegligible
values of the jitter, the largest SNR mean obtained will not occur when the SSME is operating at the true
data rate, and so the data rate will be estimated erroneously. Furthermore, the estimated SNR will be
far from its true value (approximately off by a factor of a power of $B$), since the data rate was incorrectly
classified.

As an example to illustrate the adverse effects of symbol-timing error on the estimation of the data
rate, consider the special case where $\epsilon = 1/4$ and we have BPSK data as in the example in Section II.B.
Suppose that the system data rate of the SSME is equal to that of the true data rate. Then depending
upon whether adjacent data symbols are the same or different, the signal portions of the I&D outputs
$y_{0,k}$ and $y_{1,k}$ will be unaltered or degraded, respectively, as shown in Fig. 3.

Just as with the example considered in Section II.B, when two adjacent data symbols are the same as
in Fig.3(a), we will obtain a valid contribution to the SNR estimate, since $y_{0,k}$ and $y_{1,k}$ will contain the
same signal component support and polarity. However, when the adjacent data symbols are different as
in Fig. 3(b), then we will have $y_{0,k} = 0$, which will severely degrade the SNR estimate. The reason for
this is that in this case, neither $|u_k^+|^2$ will be a good measure of the signal plus noise powers, nor will
$|u_k^-|^2$ be a good measure of the noise power. Instead, $|u_k^+|^2$ and $|u_k^-|^2$ will be measures of essentially the
same quantity, namely a combination of half of the signal power together with the full noise power. This
will result in a poor estimate of the SNR.

![Fig. 3. Signal component of the I&D outputs $y_{0,k}$ and $y_{1,k}$ when the symbol-timing error is $\epsilon = 1/4$ for the
case of (a) identical and (b) different adjacent data symbols.](image)

A. Accounting for the Symbol-Timing Error

To account for the presence of symbol-timing error, typically a digital transition tracking loop (DTTL)
is used [5]. However, a typical DTTL requires knowledge of both the carrier phase and data rate in order
to operate properly. Thus, it appears as though there is a dilemma. The data-rate estimation algorithms
of Sections II.C and II.D cannot reliably estimate the data rate (or the SNR for that matter) in the
presence of symbol-timing error, and the symbol-timing error cannot be estimated without knowledge of
the data rate (as well as the carrier phase).

To overcome this dilemma, we will exploit the fact that on average, the presence of symbol-timing error only has a deleterious effect on the SNR estimate as shown in [3]. The approach that will be taken
here is to quantize the assumed symbol-timing error to a finite number of levels. Then, for each data
rate, the SSME is run for each quantized jitter value. The SNR is then estimated to be the largest SNR
obtained while the jitter is estimated as the value which yielded the largest SNR mean. In this way, not
only do we obtain an improved estimate of the SNR for each assumed data rate, but we also obtain a
coarse estimate of the symbol-timing error itself.
Hence, we generalize the data-rate estimation algorithms of Sections II.C and II.D to jointly estimate the data rate, SNR, and symbol-timing error. Even with a coarse quantization of the symbol-timing error, this leads to a rather robust estimation of the data rate in the presence of jitter, as will be shown through simulations in Section V. Once a reliable estimate of the data rate has been made, the DTTL can then be used to obtain a finer estimate of the symbol-timing error. Furthermore, the coarse estimate of the jitter can be used as an initial condition for the DTTL, which may reduce the computation time required for convergence.

It should be noted that this approach is different from the one suggested in [3] in which oversampling is used to obtain a coarse estimate of the symbol-timing error. There, the data rate is assumed to be known and the jitter is estimated by exploiting the fact that the presence of symbol-timing error becomes less noticeable as the oversampling ratio $L \to \infty$. This approach doesn’t necessitate a modification to the SSME structure shown in Fig. 1, whereas the method suggested here does, as we show in the next section.

IV. Quantization of the Symbol-Timing Error

As the data rate of the received signal is not known a priori, at the receiver, we are only at liberty to independently quantize the symbol-timing error corresponding to one specific data rate. The reason for this is that by quantizing the jitter corresponding to one data rate, the quantized jitter values for the remaining rates are automatically determined. In order to ensure that we have, say, at least $N_{\epsilon,b}$ quantization levels for all rates, we must quantize the symbol-timing error corresponding to the highest rate by at least $N_{\epsilon,b}$ levels. The reason for this is that if the highest data-rate symbol-timing error is quantized to $N_{\epsilon,b}$ steps, then the number of jitter steps at the next lowest rate will be $BN_{\epsilon,b}$. By inductive argument, the number of quantization levels of the symbol-timing error at the $k$th lowest data rate will be $B^k N_{\epsilon,b}$.

Following this logic, at the receiver, the symbol-timing error $\epsilon$ will be assumed to be uniformly quantized to $\tilde{\epsilon} = n/N_{\epsilon,s}$ for some $0 \leq n \leq N_{\epsilon,s} - 1$, where we have

$$N_{\epsilon,s} = B^{\ell_{\text{max}} - \ell_s} N_{\epsilon,b}$$

(5)

Here, $N_{\epsilon,b}$ denotes the basic number of jitter quantization steps (i.e., the number of steps at the highest data rate), whereas $N_{\epsilon,s}$ denotes the system number of jitter quantization steps (i.e., when the assumed data-rate power is $\ell_s$).

As the number of quantization steps increases exponentially as the assumed data rate decreases, it is tempting to think that we will always obtain a better estimate of the data rate, SNR, and symbol-timing error for lower true data rates than for higher rates. However, this is offset by the fact that for a fixed observation time interval, we will obtain an exponentially larger number of observations for higher true data rates than for lower ones. Hence, we have an implicit trade-off between the number of signal observations and the number of jitter quantization levels for each true data rate.

One of the advantages of uniformly quantizing the symbol-timing error to $N_{\epsilon,s}$ steps as in Eq. (5) is that it leads to an efficient all-digital implementation of the SSME system, as we now proceed to show.
A. All-Digital Implementation of the SSME-Based Data-Rate Estimator

Prior to processing the received signal \( y(t) \) from Eq. (1) through the SSME, suppose that it is finely integrated and sampled to obtain the discrete-time signal \( y_m \) using the system of Fig. 4. Here, \( T_{\text{min}} \) is the time resolution period given to be

\[
T_{\text{min}} = \frac{T_b}{B^{\ell_{\text{max}}} N_{\epsilon, b}^m} = \frac{1}{N_{\epsilon, b}^m (B^{\ell_{\text{max}}} R_b)}
\]

Note that \( T_{\text{min}} \) is \( N_{\epsilon, b}^m \) times smaller than the shortest possible data symbol interval. Equivalently, \( 1/T_{\text{max}} \) is \( N_{\epsilon, b}^m \) times larger than the highest possible data rate, as can be seen from Eq. (2).

To generalize the SSME structure of Fig. 1 to account for the quantized symbol-timing error, it is also necessary to generalize it to account for computing an ensemble average of the observed SNRs. Recall from Section II.C that an ensemble average of the observed SNRs is required in order to estimate the mean of the SNR of the SSME system. To do this, we partition the discrete-time signal \( y_m \) into blocks over which the SNR is to be computed. For each block, the SSME computes an estimate of the SNR, and then an ensemble average of the SNR is computed over the blocks.

Let \( N_o \) denote the basic number of symbols to observe per block to obtain an SNR estimate (i.e., the number of symbols to observe per block at the lowest rate), and let \( N_b \) denote the number of blocks over which to compute an ensemble average of the SNR. Then, an all-digital implementation of the SSME system of Fig. 1 that accounts for the quantized symbol-timing error and ensemble averaging of the observed SNRs is shown in Fig. 5.

There are several things to note regarding the structure shown in Fig. 5. First, notice that the I&D half-symbol integrators from Fig. 1 can be replaced with discrete summations, which is analogous to the sampled version of the SNR estimator discussed in [3]. Furthermore, note that all of the signals starting from the half-symbol integrator outputs are indexed with a semicolon followed by \( n \). This notation was chosen here to reflect the fact that these quantities are parameterized by the quantized symbol-timing error \( \hat{\epsilon} = n/N_{\epsilon, s}^m \), where the parameter \( n \) is an integer in the range

\[
0 \leq n \leq N_{\epsilon, s}^m - 1 \iff 0 \leq n \leq B^{\ell_{\text{max}}-\ell_s} N_{\epsilon, b}^m - 1
\]

Finally, note that to form a single SNR estimate a total of \( B^{\ell_s} N_o \) samples are squared and accumulated. This was chosen as such here to keep the total observation time interval or epoch per block fixed.

By tracing the temporal indices \( m, k, \) and \( q \) from Fig. 5 backwards, it can be seen that in order to have \( 0 \leq q \leq N_b - 1 \) as desired, we need

\[
0 \leq k \leq (B^{\ell_s} N_o) N_b - 1
\]
From this, it is clear that \( k \) must vary over an interval of \( N_b \) blocks each of size \( B^t N_o \), as desired and expected. Finally, from this range of the index \( k \), in order to be able to accommodate all \( N_{e,n} \), values of the parameter \( n \), it can be shown that the time index \( m \) should vary over the interval

\[
0 \leq m \leq \left( N_{e,b} B^{t_{\max}} \right) (N_o N_b + 1) - 2 \quad (6)
\]

To incorporate the estimation of the quantized symbol-timing error, the only required modification to the data-rate estimation algorithms of Sections II.C and II.D is that the SNR estimate \( \hat{\mu}_{R;n} \) must be calculated for each \( n \). For a fixed assumed data rate, the SNR is chosen to be the largest value of \( \hat{\mu}_{R;n} \) while \( n \) is chosen to be the maximizing value of \( \hat{\mu}_{R;n} \). This modification is described in the following algorithms.

**B. SSME Data Rate/SNR/Symbol-Timing Error Estimation Algorithm**

1. Calculate the sequence \( y_m \) from Fig. 4 over the range of values given in Eq. (6).
2. Run the SSME of Fig. 5 at the highest data rate, \( R_s = B^{t_{\max}} R_b \). Calculate \( \hat{\mu}_{R;n} \) for all \( n \) and define \( n_0 \triangleq \arg \max_n \hat{\mu}_{R;n} \) and \( \hat{\mu}_{R;0} \triangleq \hat{\mu}_{R;n_0} \). Set \( i = 1 \).
3. Lower the assumed data rate by one step, i.e., set \( R_{s,\text{new}} = R_{s,\text{old}}/B \), and run the SSME. Calculate \( \hat{\mu}_{R;n} \) for all \( n \) and define \( n_i \triangleq \arg \max_n \hat{\mu}_{R;n} \) and \( \hat{\mu}_{R;i,0} \triangleq \hat{\mu}_{R;n_i} \).
4. If \( \hat{\mu}_{R;i} \geq \hat{\mu}_{R;i-1} \), increment \( i \) by 1 and go to Step (3). Otherwise, estimate the data rate, SNR, and symbol-timing error as follows:

\[
\hat{R} = B^{t_{\max}-(i-1)} R_b
\]

\[
\hat{\mu}_{R} = \hat{\mu}_{R;i-1}
\]

\[
\hat{\epsilon} = \frac{n_{i-1}}{B^{t_{\max}-(i-1)} N_{e,b}} - 1
\]
As mentioned above, for each assumed data rate, the SSME is run for each value of the quantized symbol-timing error. The SNR and jitter for that data rate then are estimated to be the largest SNR and the jitter value leading to this maximum SNR. Like the algorithm of Section II.C, this data-rate estimation technique halts as soon as the condition \( \hat{\mu}_{R_i} \geq \hat{\mu}_{R_{i-1}} \) is not satisfied. This may lead to a premature termination of the algorithm, as described in Section II.C. To prevent a premature halting of the algorithm, a GLRT-type modification to the algorithm of Section IV.B is proposed, similar to what was proposed in Section II.D.

C. GLRT-Type SSME Data Rate/SNR/Symbol-Timing Error Estimation Algorithm

1. Calculate the sequence \( y_m \) from Fig. 4 over the range of values given in Eq. (6).

2. Run the SSME for all data rates and all possible quantized symbol-timing error values. Let \( \hat{\mu}_{R(i,n)} \) denote the estimate of the mean of the SNR for the \( i \)th largest data rate with quantized jitter value \( n \). (Here we have \( 0 \leq i \leq \ell_{\text{max}} - 1 \) and \( 0 \leq n \leq B^{\ell_{\text{max}}-i} N_{\epsilon,b} - 1 \).)

3. Let \( i_{\text{opt}} \) and \( n_{\text{opt}} \) denote the indices for which \( \hat{\mu}_{R(i,n)} \) reaches its maximum value, i.e., \( i_{\text{opt}} \) and \( n_{\text{opt}} \) are such that \( \hat{\mu}_{R(i_{\text{opt}},n_{\text{opt}})} = \max_{i,n} \hat{\mu}_{R(i,n)} \). Then, estimate the data rate, SNR, and symbol-timing error as follows:

\[
\hat{R} = B^{\ell_{\text{max}}-i_{\text{opt}}} R_b
\]

\[
\hat{\mu}_R = \hat{\mu}_{R(i_{\text{opt}},n_{\text{opt}})}
\]

\[
\hat{\epsilon} = \frac{n_{\text{opt}}}{B^{\ell_{\text{max}}-i_{\text{opt}}} N_{\epsilon,b} - 1}
\]

This GLRT-type estimation algorithm is based on the principle that the true data rate and symbol-timing error should yield the largest value of the mean of the SNR. Incorrect values of these quantities, on the other hand, should lead to a degraded estimate of the SNR mean. As opposed to the previous algorithm, which lowers the assumed data rate until the SNR decreases, this algorithm computes the SNR for all data rates and all jitter values. The advantage to this is that it can prevent the algorithm from prematurely terminating, which can easily happen when the true SNR is low. This is especially the case when the true data rate is low, as we show through simulations in the next section.

V. Simulation Results for the SSME-Based Estimation Algorithms

In order to properly evaluate the performance of the estimation algorithms of Sections IV.B and IV.C, we must consider different metrics for each of the parameters that we wish to estimate. Prior to presenting simulation results, we introduce these metrics and justify their usage here.

A. Performance Metrics Used for Evaluating the Estimation Algorithms

For all of the following measures used, we assume that the estimation algorithms have each been run for a total of \( N_t \) trials. Parameters estimated at the \( n \)th trial (where \( 0 \leq n \leq N_t - 1 \) for simplicity) are denoted with a superscript surrounded by parentheses. For example, the data rate estimated at the \( n \)th trial is denoted as \( \hat{R}^{(n)} \).

1. Probability of Data-Rate Misclassification. In order to assess the performance of the algorithms with respect to estimating the data rate, one valid measure of performance is the empirical probability of data-rate misclassification, which is defined as
\[ P_m \triangleq \frac{1}{N_t} \sum_{n=0}^{N_t-1} I(\hat{R}^{(n)} \neq R) \]  \hspace{1cm} (7)

where \( I(X) \) is an indicator function that is unity if the event \( X \) is true and zero if \( X \) is false. From Eq. (7), it is clear that \( 0 \leq P_m \leq 1 \) and that \( P_m \) is a linear measure of the number of times each algorithm fails to estimate the data rate correctly.

2. Mean-Squared SNR Decibel Estimation Error. To properly gauge the performance of the estimation algorithms with respect to estimating the SNR, we seek a metric that penalizes the error between the estimated and true SNRs based on the value of the true SNR. In particular, small differences in SNR should be penalized more so if the true SNR is small than if it is large. For example, if the true SNR is 1 and the SNR is estimated to be 0.7, then it is reasonable to penalize this error more so than if the true SNR was 100 and the estimated SNR was 97.

One metric that penalizes the error in the SNR in such a way is the mean-squared error between the estimated and true SNRs in decibels (dB). This measure is the mean-squared SNR decibel estimation error and is given as follows:

\[ \xi_R \triangleq \frac{1}{N_t} \sum_{n=0}^{N_t-1} \left| \hat{R}^{(n)} \text{ (dB)} - R \text{ (dB)} \right|^2 = \frac{1}{N_t} \sum_{n=0}^{N_t-1} 10 \log_{10} \left( \frac{R}{\hat{R}} \right) \left( \hat{R}^{(n)} \right) \]  \hspace{1cm} (8)

From Eq. (8), it is clear that for low true SNR, a deviation from the true SNR is penalized more so than for high true SNR. For the example from above, the mean-squared SNR decibel error for the case of a true SNR of 1 and an estimated SNR of 0.7 is 2.399, whereas the error for the case of a true SNR of 100 and an estimated SNR of 97 is 0.017.

3. Mean-Squared Minimum Distance Symbol-Timing Estimation Error. In order to quantify the performance of each of the algorithms with respect to symbol-timing error, it is tempting to consider a simple mean-squared error measure between the true and estimated symbol-timing error, which is given as

\[ \xi_\epsilon = \frac{1}{N_t} \sum_{n=0}^{N_t-1} |\epsilon - \hat{\epsilon}^{(n)}|^2 \]  \hspace{1cm} (9)

The problem with using the metric given in Eq. (9) is that both symbol-timing errors are assumed to be in the interval \([0, 1]\). However, in reality, each symbol-timing error can be shifted by any integer amount without loss of generality. For example, if the estimated jitter is \( \hat{\epsilon}^{(n)} = 0.75 \), this is also equivalent to \( \hat{\epsilon}^{(n)} = \cdots, -1.25, -0.25, 0.75, 1.75, 2.75, \cdots \). This shifting property can cause the metric given in Eq. (9) to be overly pessimistic in certain cases.

To see this, consider the case where the true symbol-timing error is \( \epsilon = 0.1 \) and the estimated value is \( \hat{\epsilon}^{(n)} = 0.9 \). Using Eq. (9), we find that \( \xi_\epsilon = 0.64 \). However, this error is overly pessimistic, since there is a shifted version of the estimated symbol-timing error (namely, \( \hat{\epsilon}^{(n)} = -0.1 \)) that is closer to the true value of \( \epsilon = 0.1 \). This is illustrated in Fig. 6. Using this shifted value of \( \hat{\epsilon}^{(n)} \), we obtain \( \xi_\epsilon = 0.04 \), which is a more appropriate value for the error between \( \epsilon \) and \( \hat{\epsilon}^{(n)} \) in this case.
Thus, a more appropriate measure of the jitter-estimation error is to find the minimum distance between the true and estimated jitters as the jitters vary over all possible shifted values. Equivalently, we can fix the true jitter to be in the interval $[0, 1)$ and find the shifted version of the estimated jitter that is closest to the true jitter. In other words, a more appropriate measure of the jitter-estimation error is to replace each term of the summation in Eq. (9) with a term of the form

$$
\min_{\ell \in \mathbb{Z}} \left\{ |\epsilon - (\ell + \hat{\epsilon}^{(n)})|^2 \right\}
$$

(10)

where we assume $\epsilon, \hat{\epsilon}^{(n)} \in [0, 1)$. Fortunately, under the assumption that $\epsilon, \hat{\epsilon}^{(n)} \in [0, 1)$, we need not look over all values of $\ell \in \mathbb{Z}$ in Eq. (10). In particular, we need only look for the minimum value over $\ell = -1, 0, 1$. To see this, note that we have

$$
0 \leq \epsilon < 1, \quad 0 \leq \hat{\epsilon}^{(n)} < 1
$$

from which we conclude

$$
-1 < \epsilon - \hat{\epsilon}^{(n)} < 1
$$

By adding $-\ell$ to all sides of the inequality, we have

$$
-\ell - 1 < \epsilon - (\ell + \hat{\epsilon}^{(n)}) < -\ell + 1
$$

Now for $|\ell| \geq 2$, it can be shown that

$$
|\epsilon - (\ell + \hat{\epsilon}^{(n)})|^2 > 1 > |\epsilon - \hat{\epsilon}^{(n)}|^2
$$

and so the term corresponding to $\ell = 0$ always has a smaller magnitude than those corresponding to $|\ell| \geq 2$. Hence, the terms corresponding to $|\ell| \geq 2$ can be ignored in the expression of Eq. (10), leaving only $\ell = -1, 0, 1$.

Thus, to ascertain the performance of the algorithms with respect to symbol-timing error, we opted to use the following mean-squared minimum distance symbol-timing estimation error:

$$
\xi_{\epsilon} \triangleq \frac{1}{N_t} \sum_{n=0}^{N_t-1} \min_{\ell=-1,0,1} \left\{ |\epsilon - (\ell + \hat{\epsilon}^{(n)})|^2 \right\}
$$

(11)
The minimization in each term of Eq. (11) ensures that we choose the closest (left-, neutral-, or right-shifted) estimated jitter to the true one.

We now proceed to present simulation results for the SSME-based data-rate estimation algorithms of Sections IV.B and IV.C.

**B. Behavior of the SSME-Based Data-Rate Estimation Algorithms as a Function of SNR**

For all of the simulations considered here, from Eq. (1), the data constellation $d_k$ used was quadrature phase-shift keying (QPSK) [1], and the residual frequency offset $\omega_r$ was set to zero. To test the data-rate estimation algorithms of Sections IV.B and IV.C, we opted to choose the following input parameters:

- $B = 2$
- $\ell_{\text{max}} = 3$
- $N_{\epsilon,b} = 2$
- $N_o = 64$
- $N_b = 16$

It should be noted that the choice of $N_o$ and $N_b$ here implies that we have an observation time epoch equal to $N_o N_b = 1,024$ lowest rate symbols. This time epoch was fixed here for all possible data rates in order to reflect the fact that we are assumed to have no a priori knowledge of the data rate. As such, this intuitively implies that on average the SSME will be able to estimate the SNR more accurately for higher data rates. The reason for this is that, for a fixed time epoch, the SSME will have more observations the higher the data rate becomes. This will result not only in an increase in the accuracy of the SNR estimate for higher data rates but also often in a better probability of misclassification and jitter-estimation error, as will soon be shown.

For a preliminary set of simulations, suppose that the symbol-timing error is zero (i.e., $\epsilon = 0$) and the true SNR $R$ is varied from $-10$ dB to $-3$ dB.\(^2\) In Fig. 7, we have plotted the probability of misclassification, $P_m$ from Eq. (7), as a function of SNR using (1) the algorithm of Section IV.B and (2) the algorithm of Section IV.C. As can be seen, the algorithm of Section IV.B outperforms that of Section IV.C for the higher data rates, but fails to do so for the lower ones. The reason for this is that the algorithm of Section IV.B often will prematurely terminate, which is beneficial for higher true data rates and detrimental for lower true ones.

One unusual phenomenon that can be observed from Fig. 7 is that the curves cross for different values of the true data rate. This appears counterintuitive, since we should expect the higher data rates to be classified correctly more often than the lower data rates (as there are a larger number of observations in these cases). However, when the true SNR is low, the factor corresponding to the number of observations in the expression for the mean of the SSME SNR estimate becomes nonnegligible (see Eq. (3) for more details). This most likely is the reason that the curves cross at lower true SNR. At higher true SNR, the mean of the SNR estimate becomes less sensitive to the number of observations and so we expect the higher rates to be classified correctly more often than the lower rates. This is indeed the case here as can be seen in Fig. 7 when the true SNR is near $-3$ dB.

\(^2\) The reason for varying the true SNR over such low values is to reflect the fact that, in the DSN, the SNR typically is rather small.
Fig. 7. Probability of data rate misclassification as a function of SNR using the algorithms of (a) Section IV.B and (b) Section IV.C.
In order to accurately compare the two algorithms, one figure of merit that can be used is the average probability of misclassification, which we denote here by $P_m$. If $p_\ell$ denotes the probability that the true data rate is $R = B^\ell R_b$ and $P_m|\ell$ denotes the probability of misclassification given that the true data rate is $B^\ell R_b$, then by the theorem of total probability [6], we have

$$P_m = \sum_{\ell=0}^{\ell_{\text{max}}} p_\ell P_{m|\ell}$$  \hspace{1cm} (12)

Assuming that the true data rates are equiprobable (i.e., $p_\ell = 1/(\ell_{\text{max}} + 1)$ for all $\ell$), Eq. (12) becomes

$$P_m = \frac{1}{\ell_{\text{max}} + 1} \sum_{\ell=0}^{\ell_{\text{max}}} P_{m|\ell}$$

A plot of $P_m$ as a function of the true SNR $R$ is shown in Fig. 8 for equiprobable data rates. From this, it can be seen that, for lower SNR, the algorithm of Section IV.B yields a better average probability of misclassification, whereas for higher SNR (above about $-7.3$ dB), the algorithm of Section IV.C performs better. Since the desired SNR for a DSN-type application is $-6$ dB or greater (in order to achieve good performance from the turbo codes expected to be used), this implies that the GLRT-type algorithm of Section IV.C is best suited here.

To further compare the two algorithms, in Fig. 9 we have plotted the observed mean-squared SNR decibel estimation error, $\xi_R$ from Eq. (8), for the algorithms of (1) Section IV.B and (2) Section IV.C. As can be seen, the estimation error always decreased monotonically with SNR for each data rate.
Fig. 9. Mean-squared SNR decibel estimation error as a function of the true SNR using the algorithms of (a) Section IV.B and (b) Section IV.C.
Furthermore, it can be seen that the error decreased almost geometrically as the data rate increased. These two phenomena are consistent with the fact that the SSME yields a better estimate of the SNR as both the true SNR and number of observations increase.

Analogous to the average probability of misclassification $\overline{P}_m$ given in Eq. (12), we can quantitatively compare both algorithms in terms of the average mean-squared SNR decibel estimation error $\overline{\xi}_R$ given by

$$\overline{\xi}_R = \sum_{\ell=0}^{\ell_{\text{max}}} p_\ell \xi_{R|\ell}$$

where $\xi_{R|\ell}$ is the SNR decibel error given that the true data rate is $R = B\ell R_b$. Assuming equiprobable data rates in Eq. (13), a plot of $\overline{\xi}_R$ as a function of the true SNR $R$ is shown in Fig. 10 for both algorithms. As can be seen, the GLRT-type algorithm of Section IV.C always outperformed that of Section IV.B, although for larger SNR (near $-3$ dB) the two performed nearly identically. This is consistent with the intuition that the two algorithms should be performing increasingly similarly as the true SNR increases since the SNR estimates are more accurate in this case.

As a final measure of comparison between the two algorithms, the observed mean-squared minimum distance symbol-timing estimation error, $\xi_e$ from Eq. (11), is shown in Fig. 11. From this, it can be seen that the algorithm of Section IV.B yielded a good estimate for the higher data rates but suffered for the lower ones. This perhaps is due to the inherent premature halting possibility of the algorithm, as discussed earlier. For the algorithm of Section IV.C, it can be seen that, at low SNR, the error is large for all rates and that, with the exception of the lowest data rate, for a fixed SNR the error decreased as the rate increased.

As before, to quantitatively compare both algorithms, we can do so by computing the average mean-squared minimum distance symbol-timing estimation error, $\overline{\xi}_e$, given by
Fig. 11. Mean-squared minimum distance symbol-timing estimation error as a function of SNR using the algorithms of (a) Section IV.B and (b) Section IV.C.
where \( \xi_{\ell,t} \) denotes the symbol-timing estimation error given that the true data rate is \( R = B' R_b \).

Assuming equiprobable data rates in Eq. (14), a plot of \( \bar{\xi}_e \) as a function of the SNR \( R \) is shown in Fig. 12. From this, it can be seen that, for low SNR, the algorithm of Section IV.B notably outperformed the algorithm of Section IV.C. Above about \(-7.1\) dB, however, the opposite scenario took place. Since the desired mode of operation for the autonomous radio is above \(-6\) dB, this implies that once again the GLRT-type algorithm of Section IV.C is best suited here. It should be noted, however, that these algorithms can be used only to obtain a coarse estimate of the symbol-timing error and that, once the data rate has been successfully classified, a finer estimate of the jitter can be obtained through the use of a DTTL [5].

C. Behavior of the SSME-Based Data-Rate Estimation Algorithms as a Function of Symbol-Timing Error

In the previous section, we considered the performance of the data-rate estimation algorithms of Sections IV.B and IV.C for a varying SNR and a fixed symbol-timing error. Here, we investigate the performance of the algorithms as a function of the jitter for fixed SNR. Since the target SNR for the autonomous radio for the DSN is above \(-6\) dB (in order to achieve good performance from the turbo codes to be used for error correction), the SNR here was fixed at \(-6\) dB.

To illustrate the effects of quantizing and coarsely estimating the symbol-timing error on estimating the data rate, suppose that the true data rate is \( R = 2R_b \). Plots of the observed probability of misclassification are shown in Fig. 13 for (1) the algorithm of Section IV.B and (2) the algorithm of Section IV.C. As can
Fig. 13. Probability of data-rate misclassification as a function of the jitter using the algorithms of (a) Section IV.B and (b) Section IV.C. (The true data rate is $\hat{R} = 2R_b$.)
be seen, for both methods the probability appears to oscillate back and forth as the jitter varies. It can be seen that both plots appear to have eight equispaced local maxima. The reason for this is due to the quantization of the symbol-timing error. Recall that, from Section V.B, the basic number of quantization levels was $N_{c,b} = 2$. This implies that at the true data rate $R = 2R_b = 2^1R_b$ the symbol-timing error is quantized to $N_{c,s} = 2^{\ell_{\text{max}} - 1}N_{c,b} = 2^2N_{c,b} = 8$ steps by using Eq. (5). These steps are equispaced about the interval $[0, 1)$ and are of the form $n/8$ for $0 \leq n \leq 7$. Every time each of the data-rate estimation algorithms is run, each method chooses the quantized value of the jitter that is the “best fit” in some sense to the true jitter. As the true jitter itself is varied, it is evident that there will be ambiguous values of the symbol-timing error that occur directly in between the quantized values. This is illustrated in Fig. 14 for the case of 8 quantization steps here. From Fig. 13, it is clear that the probability of misclassification becomes locally maximal almost precisely at these ambiguous jitter-value locations.

To further observe the effects of varying the symbol-timing error, a plot of the observed mean-squared SNR decibel error is shown in Fig. 15 for both algorithms. Note that, unlike the probability of misclassification, for both methods the error in estimating the SNR remains approximately constant as the jitter is varied. The reason for this robustness most likely comes from the fact that, with a sufficient number of quantization steps, the “best fit” jitter value to the true one chosen for the SSME will incur only a small degradation in the mean of the SNR estimate. See [3] for more details as to the quantitative amount of this degradation.

As a final measure of the effects of varying symbol-timing error on the data-rate estimation algorithms of Sections IV.B and IV.C, a plot of the observed mean-squared minimum distance jitter-estimation error for each algorithm is shown in Fig. 16. Like the probability of misclassification plots of Fig. 13, it can be seen that the error for both algorithms oscillates back and forth as the jitter varies. Also as before, each plot appears to have eight equispaced local maxima that occur approximately at the locations corresponding to the ambiguous values of the symbol-timing error. This observation is consistent with the intuition that the estimation process should suffer the most degradation at the ambiguous jitter values. One new phenomenon that can be observed from the plots of Fig. 16 is that, for both algorithms, the error appears symmetric about $\epsilon = 1/2$ and seems to generally increase as $\epsilon \to 1/2$ from either direction. The reason for this phenomenon is not clear at this point and requires further investigation.

At this point, a few comments are in order. Had the above simulations been run for another true data rate, say at $R = 4R_b$, then there would have been 4 ambiguous jitter values instead of 8, since $N_{c,s} = 2^{3-2}N_{c,b} = 4$ in this case. The same observations regarding the performance metrics would still hold true, with the exception that the degradation in performance due to fewer jitter quantization steps would be more pronounced. In general, with a true data rate of $R = B^\ell R_b$, the number of symbol-timing error quantization steps at the true data rate is $N_{c,s} = B^{\ell_{\text{max}} - \ell}N_{c,b}$, from Eq. (5). This suggests that an

![Fig. 14. Example showing the quantized symbol-timing error values for $N_{c,b} = 8$ along with the ambiguous jitter values.](image)
Fig. 15. Mean-squared SNR decibel estimation error as a function of the jitter using the algorithms of (a) Section IV.B and (b) Section IV.C. (The true data rate is $R = 2R_b$.)
Fig. 16. Mean-squared minimum-distance symbol-timing estimation error as a function of the jitter using the algorithms of (a) Section IV.B and (b) Section IV.C. (The true data rate is $R = 2R_c$.)
implicit trade-off in performance exists between the data rate and the granularity of the symbol-timing error. For a fixed observation time epoch of the received signal, the higher the data rate, the more observations we have to help improve the estimate of the mean of the SNR of the SSME. However, at the same time, we also have an increased sensitivity to the symbol-timing error in this case. Conversely, the lower the data rate, the fewer samples there are to estimate the mean of the SNR. However, at the same time, we also have more robustness with respect to the symbol-timing error.

The effect of increasing the basic number of symbol-timing error quantization steps \( N_{c,b} \) is to increase the number of ambiguous jitter values but at the same time to decrease the degradation at these values. Thus, the estimation becomes more robust in this case. However, this comes at the price of increased computational complexity, as well as an increase in the oversampling rate of the received signal. For the Electra radio [2], the sampling rate is 4 times the highest data rate, and so the maximum value of \( N_{c,b} \) that can be used for this system is \( N_{c,b} = 4 \). Although this value may appear to be small, for most applications this should be sufficient for estimating the data rate and SNR reasonably well. As mentioned above, once the data rate has been classified correctly, the symbol-timing error can be finely estimated through the use of a DTTL [5].

VI. Concluding Remarks

The joint data rate/SNR/symbol-timing error estimation algorithms presented here were shown to be robust to the effects of jitter and performed well even in the low-SNR region typically seen in the DSN. Furthermore, due to the special structure of the SSME, little to no a priori knowledge is required for the algorithms to operate properly. For example, as the SSME computes an estimate of the SNR based on accumulated magnitude-squared quantities, the algorithms are applicable to any constant modulus constellation, including \( M \)-PSK for any \( M \). This applicability is especially important in an autonomous receiver setting.

In addition to estimating the data rate, SNR, and jitter, the algorithms presented here also can be generalized to estimate the pulse shape. Though only rectangular NRZ pulses were considered here, the algorithms can easily be generalized to estimate any piecewise constant pulse shape such as the Manchester pulse. This is accomplished by first replacing the half-symbol integrators in Fig. 5 with digital half-symbol matched filters, where the matched filters correspond to the possible pulse type being used. The SSME-derived algorithms then are run as before for each type of pulse shape. Similar to the way in which the symbol-timing error was estimated, the pulse shape yielding the largest SNR is classified as the true pulse shape. This results in a GLRT-type estimate of the pulse shape.

Note that the approach taken here for estimating the data rate autonomously consisted of simultaneously estimating the SNR and symbol-timing error along with the data rate. By constructing an SSME for each possible pulse shape, we can extend this simultaneous estimation to include classification of the pulse shape, as discussed above. The impetus for this simultaneous estimation of multiple parameters is that, in an autonomous setting, it is difficult, if not impossible, to estimate any one parameter independently without knowledge of any of the others. As a result, the algorithms proposed here are intended to serve as a coarse estimate of the desired parameters. Once these coarse estimates have been made, finer estimates of several of these parameters can then be obtained using more specialized techniques that require more side information. For example, from the coarse estimates of the data rate, SNR, jitter, and pulse shape, we can obtain a finer estimate of the symbol-timing error using a DTTL [5] and a more confident estimate of the pulse shape using the statistically optimal ML criterion [7].
