Since its founding, NASA has been dedicated to the advancement of aeronautics and space science. The NASA Scientific and Technical Information (STI) Program Office plays a key part in helping NASA maintain this important role.

The NASA STI Program Office is operated by Langley Research Center, the Lead Center for NASA's scientific and technical information. The NASA STI Program Office provides access to the NASA STI Database, the largest collection of aeronautical and space science STI in the world. The Program Office is also NASA's institutional mechanism for disseminating the results of its research and development activities. These results are published by NASA in the NASA STI Report Series, which includes the following report types:

- **TECHNICAL PUBLICATION.** Reports of completed research or a major significant phase of research that present the results of NASA programs and include extensive data or theoretical analysis. Includes compilations of significant scientific and technical data and information deemed to be of continuing reference value. NASA's counterpart of peer-reviewed formal professional papers but has less stringent limitations on manuscript length and extent of graphic presentations.

- **TECHNICAL MEMORANDUM.** Scientific and technical findings that are preliminary or of specialized interest, e.g., quick release reports, working papers, and bibliographies that contain minimal annotation. Does not contain extensive analysis.

- **CONTRACTOR REPORT.** Scientific and technical findings by NASA-sponsored contractors and grantees.

- **CONFERENCE PUBLICATION.** Collected papers from scientific and technical conferences, symposia, seminars, or other meetings sponsored or cosponsored by NASA.

- **SPECIAL PUBLICATION.** Scientific, technical, or historical information from NASA programs, projects, and missions, often concerned with subjects having substantial public interest.

- **TECHNICAL TRANSLATION.** English-language translations of foreign scientific and technical material pertinent to NASA's mission.

Specialized services that complement the STI Program Office's diverse offerings include creating custom thesauri, building customized databases, organizing and publishing research results . . . even providing videos.

For more information about the NASA STI Program Office, see the following:

Magnetic component designers are always looking for improved soft magnetic core materials to increase the efficiency, temperature rating and power density of transformers, motors, generators and alternators, and energy density of inductors. In this paper, we report on the experimental investigation of commercially available cobalt-based amorphous alloys which, in their processing, were subjected to two different types of magnetic field anneals: A longitudinal magnetic field anneal or a transverse magnetic field anneal. The longitudinal field annealed material investigated was Metglas® 2714A. The electrical and magnetic characteristics of this material were investigated over the frequency range of 1 to 200 kHz and temperature range of 23 to 150 °C for both sine and square wave voltage excitation. The specific core loss was lower for the square than the sine wave voltage excitation for the same maximum flux density, frequency and temperature. The transverse magnetic field annealed core materials include Metglas® 2714AF and Vacuumschmelze 6025F. These two materials were experimentally characterized over the frequency range of 10 to 200 kHz for sine wave voltage excitation and 23 °C only. A comparison of the 2174A to 2714AF found that 2714AF always had lower specific core loss than 2714A for any given magnetic flux density and frequency and the ratio of specific core loss of 2714A to 2714AF was dependent on both magnetic flux density and frequency. A comparison was also made of the 2714A, 2714AF, and 6025F materials to two different tape thicknesses of the polycrystalline Supermalloy material and the results show that 2714AF and 6025F have the lowest specific core loss at 100 kHz over the magnetic flux density range of 0.1 to 0.4 Tesla.

Nomenclature

- $I^2R$ windings power losses measured in Watts
- $B-H$ hysteresis plot of magnetic flux density $B$ versus magnetic field intensity $H$
- SCL specific core loss measured in Watts per pound, Watts per cubic meter, or Watts per cubic centimeter
- $B_M$ maximum magnetic flux density measured in Tesla
- $f$ electrical frequency measured in Hertz
- $i_p(t)$ the primary excitation current measured in Amperes
- $e_s(t)$ the secondary induced voltage measured in volts
- $T$ the core temperature measured in Celsius

I. Introduction

Almost all power electronic circuits, such as inverters and converters, require power magnetic components. These magnetic components function as either power transfer or energy storage devices, and in some cases fulfill both needs. Increasing the operating frequency of the power magnetic components will reduce their mass and size. Increasing their operating temperature will admit smaller cooling radiators or heat sinks and also reduce the complexity of the heat transport system.
Magnetic components designers are always looking for improved soft ferromagnetic core materials to increase the efficiency, temperature rating and power density of transformers, motors, generators and alternators, and energy density of inductors. The primary means to increase the transformer’s efficiency is to decrease the loss in the magnetic core material and the $I^2R$ or Joulean loss in the windings. The primary means to increase the transformer’s power density is to increase the frequency. But increasing the frequency without a decrease in the magnetic flux density will increase the core loss. So in most instances, the trade-off between power density, efficiency, and temperature rise comes down to a trade between operating frequency and magnetic flux density of the magnetic core material and current density in the windings. It should be noted that increasing the frequency will also increase the $AC I^2R$ loss in the windings.

A very essential element in the design of power magnetic components is the knowledge of the electrical and magnetic properties and characteristics of available soft magnetic core materials. Properties such as saturation induction, Curie temperature, and thermal conductivity can generally be obtained from the product literature provided by the manufactures and fabricators of soft magnetic materials. However, experimental characterization data such as the effect of temperature, frequency, flux density, lamination or tape thickness, and excitation waveform on the core loss and dynamic $B-H$ hysteresis loop are not always readily available. In many instances neither the manufacturer’s product literature nor the technical literature provide the required information. This almost total lack of information is particularly true for non-sinusoidal excitation core loss data. In most power electronic circuits such as switched mode power supplies, the excitation voltage impressed on the converter’s transformer is non-sinusoidal, and in DC-DC converters such as the push-pull and bridge converters, voltage excitation waveform is a square wave. Because of this lack of non-sinusoidal excitation core loss data, the transformer designer for switched mode power supplies, must generally fall back to using core loss data obtained for sine wave voltage excitation, assuming that even this data exists. Because of this lack of design data, the NASA Glenn Research Center initiated an experimental program to investigate the electrical and magnetic characteristics of candidate soft magnetic materials for temperatures up to 300 °C and frequencies up to 1 MHz for both sine and square wave voltage excitations.

The core loss, that is, the power loss, of soft magnetic materials is a function of the excitation frequency, magnetic flux density, temperature, type of excitation (voltage or current), excitation waveform (sine, square, etc.), and lamination or tape thickness. A summary of core loss theory is given in Reference 8. In previously published papers\textsuperscript{2,3,4,5,6,7,8} we have reported on the specific core loss, $SCL$, and dynamic $B-H$ hysteresis loop behavior for several polycrystalline, nanocrystalline, and amorphous soft magnetic materials. In this previous research we investigated the effects of magnetic flux density, frequency, temperature, tape thickness, and excitation waveform for voltage excitation on the $SCL$ and dynamic $B-H$ hysteresis loops. The soft magnetic materials investigated included an 80Ni-Fe polycrystalline alloy\textsuperscript{2,3,6,8}, two 50Ni-Fe polycrystalline alloys\textsuperscript{1}, a 2V-49Fe-49Co polycrystalline alloy\textsuperscript{2}, a grain oriented 3Si-Fe polycrystalline alloy\textsuperscript{3}, two iron-based amorphous alloys\textsuperscript{3,4}, two cobalt-based amorphous alloys\textsuperscript{3}, and an iron-based nanocrystalline alloy\textsuperscript{7}.

The difference in core loss and $B-H$ loop behavior resulting from either a sine or square wave voltage excitation was previously investigated by C.H. Chen\textsuperscript{9}, T. Sato and Y. Sakaki\textsuperscript{10}, and G.E. Schwarze, W.R. Wieserman, and J.M. Niedra\textsuperscript{6}. Chen investigated several materials and depending on material and flux density, the test frequencies ranged between 10 and 100 kHz. Chen found for like conditions of maximum magnetic flux density, $B_M$, and frequency, $f$, that the core loss was larger for sine wave than for square wave voltage excitation. Sato and Sakaki tested materials similar to those investigated by Chen, but extended the test frequency up to 1 MHz. Their results were similar to those reported by Chen. In these papers there is no indication that their tests were conducted for temperatures beyond 50 °C. Schwarze, Wieserman, and Niedra did extensive experimental tests on an 80Ni-Fe alloy known in the trade as Supermalloy. Their investigation covered the frequency range of 1 kHz to 50 kHz and temperature range of 23 to 300 °C. An analytical investigation of the sine and square wave $SCL$ always found that the sine wave $SCL$ for the same $B_M$, $f$, and $T$ was always greater than the square wave $SCL$. It was also found that the ratio of sine-to-square $SCL$ varied up to 22 percent\textsuperscript{6} depending on $B_M$, $f$, and $T$.

In this paper, we will report on an experimental investigation of commercially available cobalt-based amorphous alloys which, in their processing, were subjected to two different types of magnetic anneals: a longitudinal or transverse magnetic field anneal. The longitudinal magnetic field anneal is applied parallel to the rolling direction and in the plane of the magnetic tape while the transverse magnetic field anneal is applied perpendicular to the rolling direction and in the plane of the tape.

We previously investigated very thin tape Permalloy (80Ni-20Fe-4Mo) type polycrystalline material and found the ¼-mil thick tape to have very low core loss. The Permalloy type materials are relatively "old" technology materials compared to the relatively “new” amorphous magnetic materials. The $SCL$ for this ¼-mil thick tape will be included in a comparison to several amorphous materials.
In addition, dynamic $B$-$H$ loops for the materials investigated in this paper will be presented to show the effects of frequency and excitation waveform on the size and shape of these loops.

II. Materials and Test Core Description

The amorphous longitudinal magnetic field annealed Metglas® 2714A test cores were wound by Magnetics, a Division of Spang and Company, in the form of a toroid with nominal tape thickness of 20 µm. The width of the tape was 0.25 inch and nominal core dimensions were OD = 1.25 inches and ID = 1.0 inch. The amorphous transverse magnetic field annealed Metglas® 2714AF, also known as MAGNAPERM®, test core was provided to NASA Glenn Research Center as a sample toroid core by Allied Signal, Inc., Parsippany, NY. The tape thickness of the toroid was also a nominal 20 µm with core dimensions of OD = 1.75 inches, ID = 0.875 inches and height = 0.375 inches.

The manufacturer’s literature for the 2714A and 2714AF gives a saturation flux density of 0.57 T, saturation magnetostriction of less than 1 ppm, Curie temperature of 225°C, crystallization temperature of 550 °C, continuous operating temperature of 90 °C, and mass density of 7.59 gm/cm$^3$. The composition of 2714A and 2714AF according to the manufacturer’s Material Safety Data Sheet in weight percent is Cobalt (75 – 90), Iron (7 - 13), Nickel (1 – 5), Silicon (7 – 13), and Boron (1 – 5).

III. Experimental Description

The measurement system used to measure, compute, plot, and display the electrical and magnetic characteristics of the test core material is shown in Figure 1. A key element of the measurement system is the power amplifier used to excite the core material. The introduction of amplitude or phase distortion by the amplifier, and this is particularly true for square wave voltage excitation, will produce erroneous core loss and $B$-$H$ dynamic loops. The method used to obtain the SCL and $B$-$H$ dynamic loops from the primary excitation current, $i_M(t)$, and the secondary induced voltage, $e_S(t)$, waveforms is described and discussed in Reference 2.

The electrical and magnetic characteristics of the 2714A material were tested over the frequency range of 1 to 200 kHz and temperature range of 23 to 150 °C for both sine and square wave voltage excitation. The electrical and magnetic characteristics of the 2714AF material were tested over the frequency range of 10 to 100 kHz for sine wave voltage excitation and 23 °C only. $B_M$ was either the saturation flux density for the low frequencies or that $B_M$ for which the SCL remained less than 100 W/lb. Particular attention was given to capturing the required waveforms in the minimum length of time.

IV. Experimental Results and Discussion

Effects of the $B_M$, $f$, and $T$ on the SCL can best be seen and analyzed for trends by plotting the data as follows:

1. SCL versus $B_M$ with $f$ as the parameter for a given $T$.
2. SCL versus $f$ with $B_M$ as parameter for a given $T$.
3. SCL versus $T$ with $f$ as parameter for a given $B_M$.

The effects of a longitudinal magnetic field anneal (2714A) and transverse magnetic field anneal (2714AF) on the SCL can be best be seen and analyzed for trends by plotting the data as follows:

1. Ratio of 2714A to 2714AF SCL versus $B_M$ with $f$ as the parameter.
2. Ratio of 2714A to 2714AF SCL versus $f$ with $B_M$ as the parameter.

A. Longitudinal Magnetic Field Anneal (2714A)

The effects of $B_M$ and $f$ on the SCL at a temperature of 23 °C for sine and square wave voltage excitation are shown in the Figure 2 and 3 plots, respectively for the 2714A material.

The curve for a given $f$ shows that the SCL tends to increase nearly linearly with increasing $B_M$ on a log-log scale for both the sine wave excitation (Figure 2a) and the square wave excitation (Figure 2b). Likewise, the plots for a given $B_M$ shows that the SCL tends to increase nearly linearly on a log-log scale with $f$ for both sine wave excitation (Figure 3a) and square wave excitation (Figure 3b). A comparison of either Figure 2a (sine wave excitation) to Figure 2b (square wave excitation) or Figure 3a (sine wave excitation) to Figure 3b (square wave excitation) shows that the SCL is larger for sine wave excitation than for square wave excitation. For example, at $B_M = 0.4$ Tesla, the ratio of sine-to-square wave SCL varies from 1.03 at 1 kHz to 1.09 at 50 kHz. In general, this is the range of variation of the sine-to-square SCL ratio for the other $B_M$ values tested. This same comparison of sine-to-square wave SCL ratio was previously done for a 1-mil thick tape Supermalloy toroid at $B_M = 0.4$ Tesla at 23 °C. In this case, the ratio varied between 1.17 and 1.22 over the frequency range of 1 to 50 kHz. This comparison readily shows that the sine-to-square wave SCL ratio is greater for the polycrystalline Supermalloy material than for the amorphous
2714A material. The reason for this rather large difference in the ratios is not readily apparent and additional experimentation and analysis will be required to determine the underlying cause. However, these results would imply that the core loss mechanism for a polycrystalline magnetic material is different than that for an amorphous magnetic material when subjected to different types of excitation.

Figure 4a (sine wave excitation) and Figure 4b (square wave excitation) plot the SCL as a function of temperature for $B_M = 0.4$ Tesla with $f$ as the parameter for the 2714A material. The “flatness” of the SCL versus $T$ curves plotted in these figures is seen to be a function of frequency. For 5 and 10 kHz, the SCL curves tend to a slight minimum at 100 °C and then increase in slope from 100 to 150 °C, but the SCL value at 150 °C is less than that at 23 °C. For 20 and 50 kHz, the slope of the SCL curves decreases slightly from 23 to 100 °C and then the slope increases from 100 to 150 °C, but the SCL value at 150 °C is greater than that at 23 °C. The relative increase in SCL at 150 °C is greater for 50 kHz than for 20 kHz compared to the SCL at 23 °C. For 100 kHz, the slope of the SCL curve shows a steady increase over the temperature range of 23 to 150 °C.

Figure 5a (sine wave excitation) and Figure 5b (square wave excitation) give a family of dynamic $B$-$H$ loops for frequencies of 1, 5, 10, 20, and 100 kHz for $B_M = 0.4$ Tesla and $T = 23$ °C for the 2714A material. A comparison of the $B$-$H$ loops in Figure 5a with those in Figure 5b shows that the shape of the loop is excitation dependent. Sine wave voltage excitation gives rounded corners at ±$B_M$ while square wave voltage excitation gives pointed corners at ±$B_M$. Both sets of loops give a good visual image of how the size or area of the loop increases with frequency due to eddy current loss. Another observation is that the ac coercive force is less for the square wave than for the sine wave excitation for a given frequency. And finally, it should be noted that loops for both sine and square wave excitation are quite symmetrical about the origin. 2714A is a “square-loop” type of material for which the ratio of remanence to maximum flux density approaches unity. “Square loop” types of materials tend to “ratchet” towards either ±$B_M$ and thus give non-symmetrical loops.

Figure 6 gives a good visual picture of a comparison of a 2714A $B$-$H$ loop for sine and square wave voltage excitation at $B_M = 0.4$ Tesla, $f = 100$ kHz, and $T = 23$ °C. It is readily seen that the square wave excitation $B$-$H$ loop fits entirely within the area of the sine wave excitation $B$-$H$ loop except for tip areas about ±$B_M$. If these two tip areas are subtracted from the area of the sine wave excitation $B$-$H$ loop, it is seen that the area (i.e., core loss) enclosed by the sine wave excitation $B$-$H$ loop is larger than the area enclosed by the square wave excitation $B$-$H$ loop.

B. Transverse Magnetic Field Anneal (2714AF)

The effects of $B_M$ and $f$ on the SCL at 23 °C for sine wave voltage excitation for the transverse annealed 2714AF material are given in Figures 7 and 8. Just as was observed for the longitudinal annealed 2714A, the curve for any given $f$ in Figure 7 shows that the SCL increases nearly linearly with increasing $B_M$ on a log-log scale. Likewise, for any given $B_M$, Figure 8 shows that the SCL increases nearly linearly with $f$ on a log-log scale.

Our primary interest in 2714AF is to compare the SCL of the transverse annealed material with the longitudinal annealed 2714A material to determine what advantage 2714A has over 2714AF. Figure 9 gives a comparison of these two material’s SCL as a function of $B_M$ with $f$ as the parameter at 23 °C; Figure 10 gives this comparison of SCL as a function of $f$ with $B_M$ as the parameter at 23 °C. Inspection of the SCL versus $B_M$ curves in Figure 10 shows that for any given $B_M$, the SCL is lower for the 2714AF than for the 2714A material for any given frequency. Likewise, inspection of the SCL versus $f$ curves in Figure 11 shows that for any given $f$, the SCL is lower for the 2714AF than for the 2714A material for any given $B_M$.

The results in Figures 9 and 10 clearly show the SCL advantages of the transverse anneal compared to the longitudinal anneal for comparable $B_M$ and $f$. However, Figures 9 and 10 do not quickly show quantifiably how much better the SCL is for 2714AF than for 2714A. By plotting the SCL ratio of 2714A to 2714AF, the clear advantage of 2714AF is readily seen. Figure 11 is a plot of the SCL ratio of 2714A to 2714AF versus $B_M$ for three frequencies at 23 °C. Figure 12 is a plot of this same SCL ratio versus $f$ for four $B_M$ values. The SCL curves in Figure 11 show that the SCL ratio decreases as $B_M$ increases with the lowest frequency giving the largest ratio. The curves in Figure 12 show that the SCL ratio decreases as $f$ increases with the lowest $B_M$ giving the largest ratio. The results in the two figures show that the SCL advantage of 2714AF over 2714A is greatest at low $B_M$ and low $f$ and that this advantage diminishes as either $B_M$ or $f$ increases. For example, at 20 kHz and $B_M = 0.1$ Tesla, the ratio is 5.4 while for this same frequency and $B_M = 0.5$ Tesla, the ratio now decreases to 1.9. At 100 kHz and $B_M = 0.1$ Tesla the ratio is 2.8 while for this same frequency and for $B_M = 0.4$ Tesla, the ratio drops to 1.4. Even though the SCL advantage diminishes with increasing $B_M$ or $f$, the fact remains that the transverse annealed 2714AF material always has lower losses than the longitudinal annealed 2714A material for the frequencies and flux densities tested.

The 2714AF dynamic $B$-$H$ loops for frequencies 20, 50, and 100 kHz at $B_M = 0.4$ Tesla and 23 °C are drawn in Figure 13. When this family of loops is compared to the family of loops for 2714A in Figure 5(a), the following is
observed: (a) The 2714A loops are more squared, i.e., have a higher remanence than the 2714AF loops, (b) the 2714AF loops are skewed or tilted to the right relative to the 2714A loops, and (c) a 2714A loop has more enclosed area than a 2714AF loop for any given frequency. A more direct comparison of the 2714A and the 2714AF dynamic $B$-$H$ loops for 100 kHz, 0.4 Tesla is displayed in Figure 14. This figure quickly shows that the 2714AF loop is entirely enclosed in the 2714A loop except for the small areas about $\pm B_M$. Figure 14 gives both a good picture of the loss advantage of 2714AF over 2714A and also the tilt of the 2714AF loop relative to the 2714A loop.

C. SCL Comparison of Different Materials

Of special interest and of great help to the magnetic component designer are SCL plots comparing various candidate soft magnetic materials over a range of flux densities and frequencies. SCL plots of this type reduce design time as they enable the designer to judiciously select the best material for the given design frequency and flux density.

Figure 15 gives a plot of the SCL versus $B_M$ at 100 kHz and 23 °C for four different materials which includes not only the 2714A and 2714AF materials reported in this paper, but also the transverse annealed amorphous 6025F material manufactured by Vacuumsonschmelze, and poly crystalline Supermalloy material. The SCL for Supermalloy is given for 1-mil and ¼-mil thick tape. Also, the SCL for both sine and square wave voltage excitation are given for 2714A. The curves in Figure 15 show that the SCL for the transverse annealed 2714AF and 6025F materials yield the lowest losses with the 6025F material giving slightly lower SCL at low flux densities and slightly higher SCL at the higher flux densities compared to the 2714AF material. This figure also shows that the SCL for the polycrystalline ¼-mil Supermalloy is much better than the longitudinal annealed 2714A for low $B_M$, but this advantage is almost eliminated as $B_M$ approaches 0.3 Tesla.

Figure 16 gives a plot of the SCL versus $f$ at $B_M = 0.1$ Tesla and 23 °C for the same materials shown in Figure 15. Again it is seen from this figure that the transverse annealed 2714AF and 6025F give the lowest SCL, but 6025F shows slightly lower SCL compared to 2714AF. Of special interest to note is that the ¼-mil Supermalloy has a lower SCL over the entire frequency range compared to the longitudinal annealed amorphous 2714A. Also it is interesting to note that the 1-mil Supermalloy has lower SCL than the 2714A up to 20 kHz.

V. Summary and Conclusion

An experimental study was conducted to investigate the combined effects of temperature and sine or square wave voltage excitation on the SCL and dynamic $B$-$H$ hysteresis loops of the longitudinal magnetic field annealed amorphous Metglas® 2714A material. For the same $B_M$, $f$, and $T$, the SCL was always lower for the square than the sine wave voltage excitation. In comparing the polycrystalline Supermalloy to Metglas® 2714A, it was found that the ratio of sine-to-square wave SCL was greater for Supermalloy than for 2714A at $B_M = 0.4$ Tesla and $T = 23$ °C. The underlying reason for this is not immediately apparent and needs to be explored if this difference is to be attributed solely to the classical eddy current loss component of the total core loss. The effect of temperature on the SCL of 21714A for both sine and square wave voltage excitation was found to be minimal from 23 to 100 °C for $B_M = 0.4$ Tesla, but with a noticeable increase in SCL from 100 to 150 °C with the increase being more pronounced with increasing frequency.

An experimental study was also conducted to investigate the effect of a transverse magnetic field annealed material on the SCL. A comparison of the SCL of 2714A (longitudinal magnetic field anneal) with 2714AF (transverse magnetic field anneal) found that 2714AF always had a lower SCL than 2714A for any given $B_M$ and $f$. In particular, it was found that the SCL ratio of 2714A to 2714AF was dependent on $B_M$ and $f$ and that the highest ratio occurred for the lowest $B_M$ and $f$ for decreasing ratio with either increasing $B_M$ or $f$.

Finally, a comparison of the 2714A and 2714AF materials was made to another transverse magnetic annealed amorphous material, 6025F, manufactured by Vacuumsonschmelze and two different tape thicknesses of the polycrystalline material, Supermalloy. From the magnetic component designer’s viewpoint, the best material to use from this comparison in terms of SCL is either 2714AF or 6025F which have comparable losses at 100 kHz from $B_M = 0.1$ to 0.4 Tesla. This comparison also shows that the ¼-mil thick tape Supermalloy has a lower SCL than the longitudinal annealed 2714A over the entire frequency range and magnetic flux density range investigated. The comparison also shows that the SCL of the 1-mil thick tape Supermalloy is competitive with the 2714A at low $B_M$ and $f$.

Magnetic component designers are always looking for improved soft magnetic core materials to increase the efficiency, temperature rating and power density of transformers, motors, generators and alternators, and energy density of inductors. In this paper, we report on the experimental investigation of commercially available cobalt-based amorphous alloys which, in their processing, were subjected to two different types of magnetic field anneals: A longitudinal magnetic field anneal or a transverse magnetic field anneal. The longitudinal field annealed material investigated was Metglas® 2714A. The electrical and magnetic characteristics of this material were investigated over the frequency range of 1 to 200 kHz and temperature range of 23 to 150°C for both sine and square wave voltage excitation. The specific core loss was lower for the square than the sine wave voltage excitation for the same maximum flux density, frequency and temperature. The transverse magnetic field annealed core materials include Metglas® 2714AF and Vacuumschmelze 6025F. These two materials were experimentally characterized over the frequency range of 10 to 200 kHz for sine wave voltage excitation and 23°C only. A comparison of the 2174A to 2714AF found that 2714AF always had lower specific core loss than 2714A for any given magnetic flux density and frequency and the ratio of specific core loss of 2714A to 2714AF was dependent on both magnetic flux density and frequency. A comparison was also made of the 2714A, 2714AF, and 6025F materials to two different tape thicknesses of the polycrystalline Supermalloy material and the results show that 2714AF and 6025F have the lowest specific core loss at 100 kHz over the magnetic flux density range of 0.1 to 0.4 Tesla.
