METAL-SILICATE SEGREGATION IN ASTEROIDAL METEORITES. J. S. Herrin and D. W. Mittlefehldt, NASA/Johnson Space Center, Houston, TX, USA (jason.s.herrin1@jsc.nasa.gov).

Introduction: A fundamental process of planetary differentiation is the segregation of metal-sulfide and silicate phases, leading eventually to the formation of a metallic core. Asteroidal meteorites provide a glimpse of this process frozen in time from the early solar system. While chondrites represent starting materials, iron meteorites provide an end product where metal has been completely concentrated in a region of the parent asteroid. A complimentary end product is seen in metal-poor achondrites that have undergone significant igneous processing, such as angrites, HED’s and the majority of aubrites. Metal-rich aubrites such as acapulcoite/lodranites, winonaites, ureilites, and metal-rich aubrites may represent intermediate stages in the metal segregation process. Among these, acapulcoite-lodranites and ureilites are examples of primary metal-bearing mantle restites, and therefore provide an opportunity to observe the metal segregation process that was captured in progress. In this study we use bulk trace element compositions of acapulcoite-lodranites and ureilites for this purpose.

Discussion: For a given starting mass, metal-silicate segregation occurs in three stages each brought about by an increase in temperature: (1) textural coarsening of silicate and metal grains, (2) formation and migration of metal-sulfide partial melts, and (3) migration of refractory metal en masse. Silicate melting and melt migration accompanies, and may facilitate, this stage. The first stage can be observed in the metamorphic stages (3-6) of ordinary chondrites which experienced an increase in mean grain size and mineral equilibrium with progressive metamorphism at subsolidus temperatures. During this stage, siderophile elements remain unfractionated in the bulk mass. The second stage begins as temperatures exceed the Fe-Ni-S cotectic (~980°C). Sulfur-
rich partial melts form and can continue to form until S is exhausted from the system. Combined textural and chemical evidence suggest that these melts readily migrate into and out of portions of the parent asteroid even in the absence of silicate melt migration and even at temperatures below the silicate solidus [2,3]. At this stage, siderophile elements become fractionated according to their solid-liquid partitioning behavior. Figure 1 shows elevated Ir/Ni in acapulcoite-lodranites and ureilites consistent with removal of S-rich metallic partial melts, which would have very low Ir/Ni. All other groups of stony asteroidal achondrites are characterized by near-chondritic or sub-chondritic Ir/Ni. Stage 3 is the near complete removal of metal from silicate. If S is effectively exhausted during stage 2, the remaining solid metal is extremely refractory, and will not melt until temperatures well above the silicate solidus. Complete loss of this remaining Fe,Ni-metal alloy by strictly mechanical means would require high degrees of silicate partial melting, deformation, or both [4]. Low siderophile element concentrations in monomict ureilites, represented by Co in Figure 1, suggest that much of their refractory metal component has indeed been lost. Ureilites are estimated to have experienced ~30% depletion of silicate partial melts to account for their chemical and mineralogic composition [5,6]. All acapulcoite-lodranites with the exception of MAC 88177 appear to retain a significant metal component. MAC 88177 is also unique in that it appears to have experienced a greater extent of silicate partial melt extraction than other clan members, estimated to exceed 10% [2,1]. Figure 2 shows that significant silicate melt loss appears to be a prerequisite for the removal of metal. The underlying cause for greater efficiency of metal segregation in ureilites could be the greater size of the ureilite parent body.

Conclusions: The acapulcoite-lodranite clan and ureilites are unique in that they preserve a depleted asteroidal mantle sequence that retains refractory primary metal in silicate matrix. In acapulcoite-lodranites, metal segregation is largely limited to extraction of metallic partial melts (stage 2), while ureilites appear to have experienced the removal of some of their refractory metal component (stage 3). This difference could be rooted in the larger size of the ureilite parent body. In the future, as more meteorites are recovered and more data is obtained on existing meteorites, other more underrepresented groups of stony asteroidal achondrites might yield similar sequences of refractory metals.
