Lightning flashes produce nitric oxide (NO) which is an important precursor for ozone in the lower atmosphere. However, the amount of production of NO by lightning globally is very uncertain, and in fact has the largest uncertainty of all of the sources of NO both man-made and natural. Better estimates of the lightning NO production are needed such that improved estimates of the role of natural and man-made sources of NO in the chemical production of ozone in the atmosphere can be made. Ozone, at the altitudes where lightning NO is an important contributor, is an effective absorber of infrared radiation, and therefore climatically important. Since satellite measurements now provide us with good estimates of the number of lightning flashes occurring globally, most of this uncertainty stems from the large range in estimates of the NO production per flash. In this paper we use a combination of models and observations to deduce the average NO production per cloud-to-ground (CG) flash and per intracloud (IC) flash during a thunderstorm that was studied by aircraft, radar, and lightning sensors over southern Germany in 1998. The storm was simulated with a cloud model, and the cloud model data were used to run a cloud-chemistry model that includes a lightning NO generation scheme. Observed lightning flash rates are input to the model and the model places each flash into appropriate regions of the storm. The winds in the model carry the NO and other trace gases through the cloud, while chemical reactions involving NO, ozone, and other species continuously occur. Various combinations of production of NO by CG and IC flashes are tested in the model and the results of each combination are compared with observations of NO taken by aircraft in the anvil of the thunderstorm. The NO production scenario with the best match to the observed NO concentrations is considered to be the most likely. For this storm a scenario of NO production with the average production per CG flash equal to that of an IC flash yielded the best results. This outcome along with similar results for a US Great Plains storm are in contrast to older literature which proposed that an IC flash makes only 10\% as much NO as a CG flash. However, the IC and CG NO production in the analyzed storm were both less than the amount assumed for a CG flash based on the literature. These results have implications for the vertical distribution of the lightning NO production since much of the IC lightning activity occurs in the middle and upper portions of the cloud. Ozone within the storm cloud decreased during the simulation due to reactions with the very strong NO plume generated by lightning. However, downwind of the storm, ozone production occurs as the NO plume dilutes.
The effects of lightning NOx production during the July 21 EULINOX storm studied with a 3-D cloud-scale chemical transport model

ABSTRACT

The July 21, 1998 thunderstorm observed during the European Lightning Nitrogen Oxides Project (EULINOX) project was simulated using the three-dimensional Goddard Cumulus Ensemble (GCE) model. The simulation successfully reproduced a number of observed storm features including the splitting of the original cell into a southern cell which developed supercell characteristics, and a northern cell which became multicellular. Output from the GCE simulation was used to drive an offline cloud-scale chemical transport model which calculates tracer transport and includes a parameterization of lightning NOx production which uses observed flash rates as input. Estimates of lightning NOx production were deduced by assuming various values of production per intracloud and production per cloud-to-ground flash and comparing the results with in-cloud aircraft observations. The assumption that both types of flashes produce 360 moles of NO per flash on average compared most favorably with column mass and probability distribution functions calculated from observations. This assumed production per flash corresponds to a global annual lightning NOx source of 7 Tg N yr⁻¹. Chemical reactions were included in the model to evaluate the impact of lightning NOx on ozone. During the storm, the inclusion of lightning NOx in the model results in a small loss of ozone (on average less than 4 ppbv) at all model levels. Simulations of the chemical environment in the 24 hours following the storm show on average a small increase in the net production of ozone at most levels resulting from lightning NOx, maximizing at approximately 5 ppbv day⁻¹ at 5.5 km. Between 8 and 10.5 km, lightning NOx causes decreased net ozone production.
1. INTRODUCTION

The nitrogen oxides NO and NO$_2$ (NO$_x$) are important trace gases in the troposphere, the presence of which in sufficient quantities may result in the photochemical production of ozone. Fossil fuel combustion, biomass burning, microbial activity in soils, and lightning are considered the four major sources of tropospheric NO$_x$ [Bradshaw et al., 2000]. Though lightning produces much less NO$_x$ than the anthropogenic sources, it is a particularly significant source because lightning produces NO$_x$ mainly in the middle and upper troposphere where it is longer lived, typically at more dilute concentrations, and, consequently, more efficient at producing ozone than in the boundary layer where the majority of NO$_x$ is emitted.

The strength of the global NO$_x$ source from lightning remains uncertain, with values in the literature ranging over an order of magnitude (3.2-26 Tg N yr$^{-1}$) [Bradshaw et al., 2000], although most recent estimates are confined to the lower half of this range as summarized in Zhang et al. [2003]. Contributing to the widely varying global estimates are uncertainties in both the total number of flashes and amount of NO$_x$ produced per flash or per meter of flash length. There is also debate regarding the relative NO production by intracloud (IC) and cloud-to-ground (CG) flashes (e.g. Ridley et al., 2005). On the basis of previous studies which suggested that IC flashes were less energetic than CG flashes (e.g. Holmes et al., 1971), many studies of lightning NO$_x$ production have assumed that production by an IC flash ($P_{IC}$) is less than production by a CG flash ($P_{CG}$). Price et al. [1997] assumed that production by an IC flash ($P_{IC}$) was one tenth of production by a CG flash ($P_{CG}$) in calculating global lightning NO$_x$ production. Gallardo and Cooray [1996] suggested that IC flashes may dissipate nearly as much energy as CG flashes and therefore $P_{IC}$ may be on the order of $P_{CG}$. Supporting the
Gallardo and Cooray [1996] hypothesis, a 2-D cloud-scale modeling study by DeCaria et al. [2000] suggested that the $P_{IC}/P_{CG}$ ratio is likely between 0.5 and 1.0, and a 3-D simulation of the same storm narrowed this range to between 0.75 and 1.0 [DeCaria et al., 2005].

Estimates of NO$_x$ production by lightning using laboratory experiments, theoretical assumptions regarding the physics of lightning flashes, data from field experiments, and global models were summarized in Zhang et al. [2003] and range from 8 to 5000 moles of NO per flash. Below we present estimates of NO$_x$ production per flash and per meter flash length obtained by various investigators using data from several recent field projects including STERAO (Stratosphere Troposphere Experiment: Radiation, Aerosol, Ozone) over northeastern Colorado in 1996, LINOX (Lightning-produced NO$_x$), in southern Germany in 1996, and EULINOX (The European Lightning Nitrogen Oxides Project) over central Europe in 1998. Estimates of NO$_x$ per lightning flash are summarized in Table 1 while estimates of NO$_x$ production per meter flash length are presented in Table 2. For the July 12 STERAO storm over Colorado, DeCaria et al. [2000] used a 2-D cloud-resolving model, and DeCaria et al. [2005] used a 3-D cloud-resolving model, anvil NO observations, and observed lightning flash rates calculated from interferometer and NLDN (National Lightning Detection Network) observations to estimate $P_{CG}$ and the likely $P_{IC}/P_{CG}$ ratio. Based on analysis of lightning interferometer and aircraft data, Skamarock et al. [2003] estimated NO$_x$ production per interferometer flash and per meter flash length produced by lightning in the July 10 STERAO storm. The interferometer flash data included many short duration flashes that likely would not be detected by other lightning detection systems. Whether or not these short duration flashes are productive of NO is an open question. If not, then the NO production per
meter in the July 10 STERAO storm would be larger than computed by Skamarock et al. [2003]. Stith et al. [1999] estimated NO production per meter flash length based on an analysis of NO spikes measured by aircraft during the same storm, as well as other STERAO storms. Using a similar approach, Huntrieser et al. [2002] estimated NO production per meter flash length for the July 21 EULINOX storm over Germany. For the same storm, an average production of NO per flash was estimated by Théry et al. [2000] based on an average flash length of approximately 30 km calculated from interferometer data (mostly IC flashes). Through analysis of CG lightning peak current data for the July 21 EULINOX storm as recorded by BLIDS (Blitz Informationsdienst von Siemens), Fehr et al. [2004] estimated $P_{\text{CG}}$ and a $P_{\text{IC}}/P_{\text{CG}}$ ratio of 1.4 which was confirmed by a cloud-resolving model simulation that included a lightning parameterization, followed by comparison with anvil NO$_x$ observations. Based on aircraft chemical measurements from LINOX, Huntrieser et al. [1998] estimated NO production per flash while Höller et al. [1999] estimated the amount of NO produced per meter flash length for the same project using lightning observations from LPATS (Lightning Position And Tracking System). All of the above estimates of NO production are based on aircraft NO$_x$ measurements in storm anvils. In contrast, Langford et al. [2004] used remote sensing techniques to measure NO$_2$ column abundances in the core region of a thunderstorm over Boulder, Colorado, and estimated a larger value of 963 moles of NO produced per CG flash. The wide range of values found using data from various field projects suggests that lightning NO$_x$ production may vary greatly between storms and individual flashes, though all estimates of lightning NO$_x$ production contain significant uncertainty because of the number of assumptions required in translating aircraft observations into NO production values. Further investigation is required to
constrain the magnitude of NO production per flash in order to reduce uncertainty in the
global source estimate.

In this study, the three-dimensional (3-D) Goddard Cumulus Ensemble (GCE)
model is used to simulate the dynamic evolution of the EULINOX thunderstorm
observed on 21 July 1998. This output is used to drive an offline cloud-scale chemical
transport model (CSCTM) which includes a parameterized lightning NOx source. The
CSCTM results are first used to estimate NOx production per CG flash and per IC flash.
The lightning parameterization used in this model represents an advancement over the
bulk approach that was developed by DeCaria et al. [2005], in that the NO production of
individual flashes is simulated in the new scheme. In an alternative parameterization,
interferometer estimates of average hourly flash length during the storm are employed in
the model to yield an estimate of NO production per meter flash length. The ability to
estimate NO production per unit flash channel length also represents an advancement in
the model over the version used in earlier work (e.g. DeCaria et al., 2005). Chemical
fields from the CSCTM are used in a chemistry-only version of the model to estimate
downstream ozone production in the 24 hours following the storm.

Fehr et al. [2004] also simulated the July 21 EULINOX storm using a cloud
resolving model with a parameterized lightning NOx source to investigate lightning NOx
production and transport, but did not examine the transport of other species, or the
chemical impact of lightning NOx during or after the storm. Lightning NOx emissions
were represented by a Lagrangian particle model with particles distributed within a
vertical lightning channel which does not account for the tortuosity of an actual lightning
flash. The Fehr et al. [2004] study also did not attempt to quantify production per meter
of flash channel length. In contrast, the research reported here considers the transport of
other species, the production of NO\textsubscript{x} per meter of flash channel length, and the resulting
photochemical ozone production/loss.

Section 2 of this paper provides background information on the EULINOX
project and the investigated thunderstorm, as well as the models used. Section 3
discusses the results of the various simulations, and section 4 contains a discussion of
conclusions drawn from this research.

2. OBSERVATIONS AND NUMERICAL MODELS

2.1. Overview of the EULINOX project and the July 21, 1998 storm

The European Lightning Nitrogen Oxides Project (EULINOX; Höller and
Schumann, 2000; Huntrieser et al., 2002) was conducted in central Europe during June
and July 1998 with the goal of better understanding lightning NO\textsubscript{x} production. During
the project, airborne measurements were collected by the Deutsches Zentrum für Luft-
und Raumfahrt (DLR) Falcon and Do228 research aircraft. Both measured NO\textsubscript{x}, O\textsubscript{3}, CO
and CO\textsubscript{2}, as well as meteorological parameters in and around thunderstorms in the region
of the experiment. The Do228 flew primarily in the boundary layer and lower
troposphere below 4 km, while the Falcon investigated the upper troposphere and
performed a number of anvil penetrations through monitored thunderstorms. CG
lightning occurrences were recorded by an LPATS system known as BLIDS. In addition,
total 3-D lightning activity (IC+CG) within the 100 km area surrounding the EULINOX
operation center was mapped by a VHF (very high frequency) interferometer from the
French Office Nationale d’Etudes et de Recherches Aerospatiales (ONERA). Both radar
and satellite observations were used to monitor the development of thunderstorms in the
region.
On the evening of 21 July 1998 the evolution of a severe thunderstorm west of Munich, Germany was documented. Figure 1 [Höller et al., 2000] shows the evolution of the thunderstorm as observed by the Polarisation Diversity Radar (POLDIRAD) radar at 1° elevation. After an initial period of intensification, the storm split into two distinct cells evident on the radar image observed at 1852 LT (1652 UTC). The northernmost cell became multicellular in structure and was observed to decay soon after the cell-splitting event, while the southern cell strengthened and developed supercell characteristics including a distinct hook echo (see radar image observed at 1933 LT; Höller et al., 2000).

From 1400 to 2200 UTC total lightning activity within the entire storm was monitored by the ONERA interferometer, and cloud-to-ground lightning activity was recorded by BLIDS. Théry [2000] compared flashes recorded by BLIDS and the ONERA interferometer and found that many low amplitude positive flashes recorded by BLIDS were IC rather than CG. This was also true for flashes with weak negative peak current, but to a lesser degree. Flashes with peak current between -5 and +15 kA are removed [Höller et al., 2000] and the remaining BLIDS flashes counted to obtain CG flash rates, which were subtracted from counts of interferometer flashes to yield IC flash rates. By comparing plots of the locations of interferometer and BLIDS flashes with plots of radar reflectivity, flashes belonging to the northern and southern cells were identified. Figure 2 shows the estimated flash rates for the northern and southern cells following the cell splitting. The southern cell contained the majority of lightning activity with IC flashes dominating the total lightning activity after 1710 UTC. In the period shown, 360 CG flashes and 2565 IC flashes were recorded in the southern cell (mean
IC/C G ratio = 7.1) while in the northern cell there were 289 CG flashes and 815 IC flashes (mean IC/C G ratio = 2.8).

The storm was penetrated seven times during the period from 1735 to 1842 UTC by the Falcon while flying between 6.3 and 9.2 km AGL near the active convective cells and in the lower anvil. Figure 3 [Huntrieser et al., 2002] shows the Falcon flight track superimposed on a map of VHF signals recorded by the interferometer from 1740 to 1810 UTC. During this period, nearly 400 IC and CG flashes were recorded. The Falcon flew between 8 and 9 km AGL in the vicinity of the maximum lightning activity where the majority of freshly produced NO would be observed. NO mixing ratios up to 25 ppbv were observed during this period [Huntrieser et al., 2002].

Fehr et al. [2004] simulated the EULINOX storm of July 21, 1998 using a modified, cloud-resolving version of the PennState/NCAR Mesoscale Model 5 (MM5) which included a parameterized lightning NOx source with emissions represented by a Lagrangian particle model. Lightning NOx particles were distributed within a vertical flash channel with the vertical distance between particles depending on atmospheric pressure. Flash rates were parameterized using the methods of Price and Rind [1992, 1993] and Pickering et al. [1998] and compared with observed flash rates. The parameterization overestimated total lightning activity considerably, so observed flash rates were used to estimate lightning NOx production by comparing model results with NO measurements taken during three of the seven Falcon anvil penetrations. A production scenario in which a CG flash produces approximately 330 moles of NO per flash and an IC flash is 1.4 times more productive of NO than a CG flash compared favorably with the observations used. An estimated 50-80% of the lightning produced
NO$_x$ was transported to the anvil region, with 97% of anvil NO$_x$ resulting from IC flashes.

2.2. Model Description

In order to simulate the July 21 EULINOX storm, the 3-D Goddard Cumulus Ensemble Model (GCE), a non-hydrostatic, cloud resolving model, was employed with a horizontal resolution of 2 km and vertical resolution of 0.5 km. The GCE uses a Kessler-type scheme for cloud water and rain [Kessler, 1969; Houze, 1993], and a three-category scheme from Lin et al. [1983] for cloud ice, snow, and hail to parameterize cloud microphysics. The open boundary conditions of Klemp and Wilhelmson [1978] are employed at the lateral boundaries. A complete description of the GCE model is given in Tao and Simpson [1993], with updates described by Tao et al. [2001].

An associated offline 3-D Cloud-Scale Chemical Transport Model (CSCTM) was developed at the University of Maryland [DeCaria et al., 2000; DeCaria et al., 2005]. Temperature, density, wind, hydrometeor (rain, snow, graupel, cloud water, and cloud ice), and diffusion coefficient fields from the 3-D GCE are read into the model every ten minutes in the simulation, and these fields are then interpolated to the model time step of 15 seconds. The transport of chemical tracers is calculated using the van Leer advection scheme. The CSCTM employs parameterizations of lightning NO$_x$ production which use observed flash rates, avoiding the difficulty of explicit modeling of thunderstorm electrification. A passive version of the CSCTM includes only the transport of tracer species and production of lightning NO$_x$ without any chemical reactions. In the passive version, the IC- and CG-produced NO$_x$ can be isolated from pre-existing NO$_x$ which allows a number of different production scenarios to be evaluated quickly. To account for the effects of chemical reactions, the full version of the CSCTM combines tracer
transport and lightning production with a chemical solver and photochemical mechanism,
better simulating the actual chemical environment within the storm. The same chemistry
reaction scheme as used by DeCaria et al. [2005] is employed here, except that reaction
schemes for isoprene and propene were added. Soluble species are removed from the gas
phase by cloud and rain water. Multiphase reactions are not included, and photolysis
rates are calculated as a function of time. A chemistry-only version of the CSCTM is
used to estimate 24-hour ozone production in the convective outflow that is assumed to
be transported downwind. In this version, chemical reactions and diffusion are included,
while cloud-scale advection is turned off. Clear sky photolysis rates are assumed and the
photolysis rates are calculated as a function of time.

Two different parameterizations are used in the model to estimate the production
of lightning NO\textsubscript{x}. These parameterization schemes differ from the lightning NO\textsubscript{x}
parameterization used in DeCaria et al. [2005] in which lightning NO\textsubscript{x} was distributed
bimodally in the vertical and uniformly to all grid cells within the 20 dBZ contour of the
cloud at each level as if the NO\textsubscript{x} was instantly diffused throughout this region of the
cloud. The DeCaria et al. [2005] model results were compared to the general profile
shape and integrated column mass of observed NO\textsubscript{x}. This approach performed well for
the July 12 STERAO storm in which the anvil observations were located relatively
distant from the convective cores. In that case, the aircraft measured the integrated
effects of many flashes on NO\textsubscript{x} mixing ratios. However, in the EULINOX storm the
aircraft flew in a much more electrically active part of the storm, necessitating a different
approach. These new parameterizations attempt to more realistically replicate actual
flashes and the range of NO\textsubscript{x} mixing ratios observed by putting lightning NO\textsubscript{x} from
individual flashes into smaller subsets of grid cells within the cloud.
The first parameterization allows an estimate to be made of NO production per flash and the second allows an estimate of production per meter flash length. In the first scheme, observed flash rates for the northern and southern cells are input along with a scenario of IC and CG production specified in terms of moles of NO produced per flash. The average horizontal extent of a flash is calculated from interferometer data and is input for each 3-minute lightning time step, as is the total number of IC and CG flashes in each cell of the storm. The areas in which lightning occurred in the northern and southern cells were estimated from plots of observed IC and CG flashes. Areas of approximately this size were centered 10 km downwind of the maximum updraft of the northern and southern cells in the model because Höller et al. [2000] noted that in this storm, based on an analysis of interferometer and radar observations, flashes tended to occur downwind of the updraft. The distance of 10 km was chosen based on visual inspection of plots of radar reflectivity overlaid with flash locations presented in Höller et al. [2000].

The vertical distribution of IC flash channel segments was derived from two Gaussian distributions, one centered at -30° C and the other at -15° C, which were summed, while the vertical distribution of CG flash channel segments consisted of a single Gaussian distribution centered at -15° C [DeCaria et al., 2005]. These distributions, f(z), determine the number of grid cells in the horizontal to be included in an IC or CG flash at each model level as shown in Figure 4a. The vertical distribution of the number of grid cells included in a CG flash results in no grid cells in the lowest two layers of the model receiving direct placement of lightning NO. To a first approximation, this configuration is supported by data from 3-D lightning mapping systems which record a nearly negligible amount of flash channels near the surface compared with that which
occurs aloft. At the top of the cloud, as determined by the uppermost nonzero value of

\( f(z) \), an initiation point is selected at random within the designated area downwind of the

updraft. After this point is selected, the flash is constrained to an area equaling the

average horizontal flash extent. At each level, the locations of a number of grid cells

given by \( f(z) \) are selected at random, such that tortuosity of the flash is simulated. NO

production is distributed to all grid cells along each flash with a dependence on pressure

as described in DeCaria et al. [2000] because of laboratory experiments showing a linear

relationship between pressure and NO production [Wang et al., 1998]. Figure 4b shows a

schematic diagram of lightning NO placement in the southern cell. The dashed line

represents the 20 dBZ contour at 9 km 150 minutes into the simulation. The maximum

updraft velocity location is identified by the triangle. The larger box centered

downstream of the updraft velocity maximum designates the area from which an

initiation point for the flash, marked with an open circle, is selected. The smaller box

centered about the initiation point is the area determined by the average horizontal flash

extent. Various NO\(_x\) production scenarios are simulated to determine which most

closely matches observed NO\(_x\) mixing ratios in the electrically active region.

The second parameterization scheme is similar to the first, except that the

specified production is per meter of flash channel length and production per flash is

calculated by the model using the average hourly length per flash as given in Théry et al.

[2000]. Lightning flashes are constructed in the same manner as in the first

parameterization, and the most appropriate production per meter flash length is estimated

by comparing results from various production scenarios with aircraft observations.

3. RESULTS

3.1. Cloud simulation
The GCE model was initialized with a single sounding that included data from a German Weather Service radiosonde, the ascent of the DLR Falcon aircraft, and a dropsonde released during the Falcon’s flight, all of which were no more than 90 minutes ahead of the storm. CAPE for this sounding was 1590 J/kg [Fehr et al., 2004]. The sounding also shows winds veering at low levels which is conducive to splitting. Convection was initiated with a warm thermal perturbation. The model domain was 360x328 km, with a horizontal resolution of 2 km. There were 50 vertical levels, with a resolution of 0.5 km. The model was run for 6 hours.

The GCE simulation successfully reproduced a number of features of the observed storm. A single cell first appears 20 minutes into the simulation. At 70 minutes, the cell splitting begins. Because the early stages of the cell splitting is observed on radar at ~ 1650 UTC (Figure 1), 70 minutes in the simulation was chosen to correspond to this time for the purposes of comparison with aircraft observations and the use of observed flash rates in the lightning parameterization. Thus, the beginning of the simulation is assumed to correspond to 1540 UTC. Figure 5 shows a time series of radar reflectivity plots calculated from the GCE model hydrometeor mixing ratios at 1 km. A single cell is observed at 30 minutes into the simulation. The cell has completely split in two at 100 minutes in the model simulation. The southern cell developed a supercell circulation and has an apparent hook echo at this time. At 150 minutes, a third cell has developed between the original two cells. The southern cell has begun to decay at 180 minutes, and the northern cell becomes dominant.

Some simulated storm features are similar to observations and some differ. The model correctly predicted the splitting of the initial cell. However, in the observed system the northern cell weakened rapidly after the cell splitting event and the southern
cell became the dominant feature, evolving into a supercell. The simulated southern cell, while demonstrating supercell characteristics and dominating for a period of time, did not persist as long as observed. Cloud top heights reached 14 km which compares favorably with observations [Höller et al., 2000] and the MM5 simulation presented by Fehr et al. [2004]. Discrepancies between the simulated storm and observations may be because the nonuniformity of terrain and initial conditions [Stenchikov et al., 2005] were not accounted for in the GCE simulation. Boundary conditions may also have contributed to these differences. However, comparison with observations showed that simulated storm evolution is fairly reasonable for the period of 180 minutes that was chosen for the chemistry-transport calculations in this study.

At 1657 UTC, just after the cell splitting event, the southern cell was observed by dual-Doppler radar and the 3-D wind field reconstructed. At this time, a maximum updraft speed of 24 m s\(^{-1}\) was observed while the strongest downdraft was 9 m s\(^{-1}\) (Höller et al., 2000). At the corresponding time in the simulation (80 minutes), the maximum updraft velocity was 34 m s\(^{-1}\) while the maximum downdraft was 7 m s\(^{-1}\). Due to the location of the storm with respect to the radars, dual-Doppler analysis was not possible at other times. Maximum updraft velocities were approximately 36 m s\(^{-1}\) between 90 and 130 minutes in the simulation, and then decreased. This is lower than the maximum updraft of 49 m s\(^{-1}\) reported in the Fehr et al. [2004] simulation. Downdraft velocities were also less than those presented in Fehr et al. [2004] in which a maximum of 25 m s\(^{-1}\) was recorded. Throughout the GCE simulation, downdraft velocities were typically less than 10 m s\(^{-1}\). Low level inflow to the storm occurred between 0.5 and 3 km while outflow from the anvil was greatest between 9 and 11 km.

3.2. Passive Model Results
The passive version of the CSCTM was used to calculate the transport of CO$_2$, NO$_x$, and O$_3$. CO, which in polluted regions has a stronger vertical gradient and would be preferable to CO$_2$ as a tracer of upward transport, was not measured on this day. An initial profile of CO$_2$ data was constructed using data from the Falcon ascent and a value of 355 ppbv above the tropopause taken from Strahan et al. [1998]. An initial profile of O$_3$ was constructed from data from the Falcon ascent, the DO-228 boundary layer data for the day, and a climatological average ozone profile for the latitude of Munich above 9 km. The NO$_x$ profile was composed of data taken from the Falcon ascent in the free troposphere and from a profile one standard deviation greater than the average NO$_x$ boundary layer profile during the EULINOX project [Huntrieser et al., 2002]. A profile with values larger than the project mean in the boundary layer was assumed because no actual measurements were available and high measured boundary layer values of CO$_2$ and O$_3$ suggested polluted NO$_x$ conditions on this day. Sensitivity calculations were also performed using the EULINOX boundary layer average and the boundary layer average plus two standard deviations in order to assess the effects of this uncertainty on the lightning NO production results. Initial condition profiles for CO$_2$, NO$_x$, and O$_3$ are shown in Figure 6. IC and CG flash rates for the northern and southern cells (as shown in Figure 2) were read into the model at 3-minute intervals beginning 21 minutes into the simulation to correspond to the time when lightning was first observed, and the amount of lightning NO$_x$ produced in each time interval is calculated.

3.2.1. CO$_2$ and O$_3$ results

Figure 7 shows a vertical cross section of CO$_2$ through the southern cell at 150 minutes when the cell was at maximum strength, oriented $65^\circ$ counterclockwise from due east. Air containing the maximum CO$_2$ mixing ratios exceeding 370 ppmv initially in the
1-2 km region has been transported to over 12 km in the core updraft region, and as high as 10 km in the anvil, indicating strong upward motion. Both the core and the downwind anvil regions of the storm are largely comprised of air that resided in the boundary layer prior to convection, while there is little evidence of entrainment of environmental air with lower CO₂ mixing ratios. The model also suggests downward transport of smaller mixing ratios of CO₂ in the 8-11 km altitude region behind the storm.

In order to compare simulated tracer transport with mixing ratios observed during the series of seven anvil penetrations, data collected by the Falcon aircraft were averaged over approximately 11-second intervals to yield a spatial resolution equivalent to the model, and then binned into 0.5 km thick layers. Unfortunately, in-cloud observations were only available for three 0.5 km thick layers centered at 8, 8.5 and 9 km AGL. Therefore, the comparison with model results includes only a 1.5-km thick layer. The analysis would have benefited from observations at a wide range of altitudes as were available for the July 12 STERAO-A storm simulated by DeCaria et al. [2005] in which the aircraft executed a spiral ascent through the storm anvil, measuring NO from 7 to 11 km MSL. The area covered by each penetration was calculated from flight position data. The average distance covered during 6 of the 7 anvil penetrations was determined to be approximately 24 km in the x-direction and 36 km in the y-direction. A box of this size was placed around the core of the southern cell where radar observations and flight data show the Falcon was primarily sampling. The grid cells within this box were sampled at times in the simulation corresponding to the times of the aircraft sampling at each level, and cumulative probability distribution functions (pdfs) were calculated for each level. In addition, the mean, mode and standard deviation of observed and simulated NOₓ, O₃ and CO₂ mixing ratios at 9 km were calculated and are shown in Table 3. The model did
an excellent job in estimating the mean values at this altitude. However, it appears that
the distribution of observed O3 mixing ratios at this level is substantially broader than
that simulated.

Figure 8 shows the calculated pdfs of observed and simulated CO2 at 8, 8.5 and 9
km AGL. At all three levels, the distribution of simulated CO2 matches the observed
distribution well with a slight overestimation of the maximum values. At 9 km, the
model also underestimates the minimum values, suggesting that the downward transport
at the rear of the storm may not have been as pronounced as seen in the model. Figure 9
shows pdfs of observed and simulated O3 at 8 and 9 km, the only two levels for which a
sufficient number of observations were available to calculate pdfs. At both levels, the
simulations underestimate the maximum values and overestimate the minimum values.
The overestimation of minimum values is due in part to the initial condition profiles used.
Though ozone as low as 63 ppbv was observed in the storm, the lowest value in the initial
condition profile was 67 ppbv at 3.5 km because there was no observational evidence
outside the storm to suggest that values lower than this would be appropriate. When
chemical reactions are included in the model (see Section 3.3.) a small loss of ozone
occurs at 8 km, slightly improving the comparison between the simulated and observed
minimum values though overestimation of the minimum values is still noticeable,
particularly at 9 km. The underestimation of the maximum values suggests the model
may be underrepresenting downward transport, although this is not supported by analysis
of the CO2 distributions. This contradiction may be the result of a lack of sufficient
observations of CO2 and O3 near the tropopause to well define the vertical gradients in
this region that are used in the initial condition profiles. Additionally, the observed
discrepancy could be caused by time interpolation of the driving field and approximation
errors. If downward transport is slightly underrepresented by the model, it is unlikely to
significantly affect the estimates of lightning NO\textsubscript{x} production because NO\textsubscript{x} mixing ratios
immediately above the tropopause are similar to the enhanced mixing ratios of NO\textsubscript{x}
between 7 and 9.5 km in the initial condition profile.

3.2.2. NO\textsubscript{x} results

To calculate lightning NO\textsubscript{x} production, P\textsubscript{CG} was estimated to be approximately
360 moles of NO per flash based on observed peak current and a relationship between
peak current and energy dissipated from Price et al. [1997]. Several different values of
the P\textsubscript{IC}/P\textsubscript{CG} ratio were simulated and the results compared with observations. The
common assumption that P\textsubscript{IC} is one tenth P\textsubscript{CG} from Price et al. [1997] was simulated and
the pdf of observed and simulated NO\textsubscript{x} at 9 km is shown in Figure 10a. The assumption
that IC flashes are significantly less productive of NO than CG flashes clearly
underestimates NO\textsubscript{x} at all levels. Fehr et al. [2004] found a P\textsubscript{IC}/P\textsubscript{CG} ratio of 1.4 most
appropriate for a simulation of the same storm. Figure 10b shows the 9 km pdf with NO\textsubscript{x}
production based on this assumption. At this level, where the majority of NO\textsubscript{x}
observations were taken, assuming a P\textsubscript{IC}/P\textsubscript{CG} ratio of 1.4 results in an overestimation of
the lightning NO\textsubscript{x} source. At 8 and 8.5 km, fewer observations are available, but the
maximum observed mixing ratios exceeding 15 and 20 ppbv were reasonably simulated
at these levels using the ratio of 1.4. Therefore the comparison of the P\textsubscript{IC}/P\textsubscript{CG} = 1.4
scenario with observations at these two levels is better than at 9 km.

A scenario in which P\textsubscript{IC} is equal to P\textsubscript{CG} was also simulated and the pdfs for 8, 8.5,
and 9 km are shown in Figure 11. At 9 km, the comparison between the observed and
simulated distributions is much better than in the P\textsubscript{IC}/P\textsubscript{CG} of 0.1 and 1.4 scenarios shown
in Figure 10. At 8 and 8.5 km, the model is able to reproduce the distribution below 6
ppbv fairly well, but fails to produce the large NO$_x$ mixing ratios observed. Figure 12a shows a plot of NO$_x$ at 9 km 180 minutes into the P$_{IC}$=P$_{CG}$ simulation with the box used for sampling model output. NO$_x$ mixing ratios exceeding 9 ppbv are evident in the core of the southern cell and mixing ratios over 2 ppbv extend outward in the anvil a distance of over 70 km. Figure 13 shows the average profiles of NO$_x$ mixing ratio within the averaging box at the beginning of the simulation, after 180 minutes of simulation of NO$_x$ transport without lightning NO production, and at 180 minutes with the inclusion of lightning NO production. The transport-only simulation results in a mean profile over the averaging box which maximizes at only 1 ppbv at anvil levels, but this represents an approximate doubling of the amount of NO$_x$ at this level compared with the initial profile. The inclusion of lightning NO$_x$ in the model results in an increase in this anvil maximum to approximately 4 ppbv at 10 km with a second peak of 4 ppbv at 5.5 km.

To determine which production scenario was the most appropriate, the mass of N in NO$_x$ in the column between 7.75 and 9.25 km was also calculated by averaging observations and model results in each of the three 0.5 km layers. The observations yield a column mass of $1.13 \times 10^{-3}$ g N m$^{-2}$. The accuracy of the NO and NO$_2$ instruments are 5 and 10% respectively [Huntrieser et al., 2002]. Therefore, in terms of measurement error in the column mass estimate, 10% would be an upper limit. However, there is additional uncertainty because it is impossible to know how well the aircraft observations represent a particular area within the storm. Assuming a production scenario in which an IC flash produces only one tenth as much NO as a CG flash greatly underestimates column mass, producing $3.43 \times 10^{-4}$ g N m$^{-2}$. The assumption from Fehr et al. [2004] that an IC flash produces 1.4 times as much NO as a CG flash leads to a column mass of $1.36 \times 10^{-3}$ g N m$^{-2}$, an overestimation of approximately 20%. Of the three scenarios
presented, assuming an IC flash produces as much NO as a CG flash provides the best comparison with observations with a column mass of $1.05 \times 10^{-3}$ g N m$^{-2}$, which underestimates the column mass calculated from observations by approximately 7%. The inclusion of chemical reactions in the model tends to decrease NO$_x$, slightly increasing the error in column mass of the production scenario in which $P_{IC}=P_{CG}=360$ moles NO per flash to 10.5% (see Section 3.3). Based on the comparison of the pdfs and column mass of the observed and simulated storms, this scenario is selected as the most appropriate of the three for this storm. An increase or decrease of one standard deviation in the boundary layer NO$_x$ resulted in a change of only 3% in the calculated column mass of N in NO$_x$. Therefore the assumption of boundary layer NO$_x$ mixing ratio has little impact on our ability to deduce the appropriate lightning NO$_x$ production scenario.

A second parameterization scheme was used to estimate NO production per meter flash channel length. In this parameterization, various values of production per meter are specified, and production per IC and CG flash is calculated using hourly average interferometer-observed flash lengths of 21.5, 27.9, and 31.4 km from Théry et al. [2000] for the hours beginning at 16, 17 and 18 UTC, respectively. By calculating pdfs (Figure 11) and column mass, a production of $1.25 \times 10^2$ moles NO per meter of flash channel length was found to yield results comparable to the $P_{IC}=P_{CG}=360$ moles NO per flash scenario, slightly underestimating column mass by approximately the same amount. Note that the pdfs are nearly identical to those from the first parameterization.

The average hourly flash lengths of Théry et al. [2000] did not differentiate between IC and CG flashes. Dotzek et al. [2000] attempted to estimate typical flash lengths for IC and CG flashes separately based on the heights of the main charge layers in the storm and the diameter of the storm with radar reflectivity greater than 30 dBZ.
Using this method, they found typical lengths of 43 km for an IC flash, 26.5 km for a negative CG flash, and 29.5 km for a positive CG flash. It should be noted that because these estimates are based not on calculated lengths of IC and CG flashes, but on other parameters, there is a high degree of uncertainty. If these numbers are used in the model instead of the average hourly flash lengths from Théry et al. [2000], then a production scenario in which an IC flash produces $8.34 \times 10^{-3}$ moles NO per meter of flash channel length and a CG flash produces $1.35 \times 10^{-2}$ moles of NO per meter of flash channel length is needed to produce a favorable comparison with observations.

3.3. CSCTM (with chemistry) results

To investigate the impact of chemistry on the concentrations of species of interest such as NO\textsubscript{x} and ozone, a CSCTM run including chemical reactions was performed. Profiles of C\textsubscript{2}H\textsubscript{6}, C\textsubscript{2}H\textsubscript{4}, C\textsubscript{3}H\textsubscript{6}, C\textsubscript{3}H\textsubscript{8}, CH\textsubscript{2}OOH, CO, H\textsubscript{2}O\textsubscript{2}, HCHO, HNO\textsubscript{3}, isoprene, and PAN were taken from a July mean profile for the appropriate latitude and longitude of the EULINOX storm computed by the 3-D global University of Maryland Chemical Transport Model (UMD-CTM) [Park et al., 2004] and are shown in Table 4. The NO to NO\textsubscript{2} ratio at each CSCTM model level was based on the ratios from the UMD-CTM, but the initial NO\textsubscript{x} was equivalent to the values used in the passive version of the model. Profiles of hydrocarbons were scaled with the aid of airborne hydrocarbon measurements collected during the 1999 Konvektiver Transport von Spurengasen (KONVEX) campaign to ensure they represented values typical of the relatively polluted German atmosphere. Boundary layer concentrations of isoprene were held constant (e.g. at 1 ppbv in the bottommost layer of the model) during daylight hours to reflect a balance between the emissions and reactive losses of these compounds. At the conclusion of the 180-minute simulation, isoprene mixing ratios were approximately 6 pptv in the core updraft region.
of the storm, and were typically less than 1 pptv in the anvil region. A 15-minute “spin-up” simulation was performed using a column model which included the same chemical reactions as the full version of the 3-D CSCTM in order to allow the species to come into equilibrium. The CSCTM was run with the parameterization which uses observed flash rates as input assuming the lightning NO\textsubscript{x} production scenario P\textsubscript{IC}=P\textsubscript{CG}=360 moles NO/flash. Column mass and pdfs were computed from the model output using the same methods as for the passive version of the model. The use of global model output along with observed NO\textsubscript{x} results in a small decrease in NO\textsubscript{x} in the initial conditions during spin-up, such that the column mass for the flash rate and flash length scenarios simulated is $1.01 \times 10^{-3}$ g N m$^{-2}$, a difference of 10.5% from the observations. A case in which no lightning NO\textsubscript{x} is included was also simulated to determine the lightning NO\textsubscript{x} effects on in-cloud chemistry.

Figure 12b shows ozone concentrations 180 minutes into the simulation at the 9 km level. Lower ozone air has been transported upwards in the convective cores and is present in the outflow of the storms. There is significant downward transport of ozone surrounding the cores of the cells, elevating ozone levels above those of the environmental air in the anvil region. At the conclusion of the 180 minute simulation, lightning NO\textsubscript{x} results in additional O\textsubscript{3} production less than 0.1 ppbv in regions outside of the cloud at 9 km. At 8 and 9 km, the inclusion of chemical reactions in the model continues to result in the underestimation of maximum ozone mixing ratios (see Figure 9), suggesting that downward transport may be underrepresented in the model.

In order to identify the effect of lightning NO\textsubscript{x} on O\textsubscript{3} production during the storm, O\textsubscript{3} concentrations are averaged at 180 minutes in the simulation within the sampling box shown in Figure 12a at each model level for both the lightning and no-lightning cases.
The values from the simulation without lightning NO$_x$ are subtracted from the values from the simulation which included a lightning NO$_x$ source. Figure 14 shows the average change in ozone due to lightning NO$_x$, as well as the maximum and minimum change at each level. During the lifetime of the storm, the injection of lightning NO$_x$ results in a net loss of ozone averaging less than 4 ppbv at all levels. The maximum net loss during this 3 hour period exceeds 9 ppbv at 5.5 km. This is due to the large quantities of NO$_x$ (up to 9 ppbv) being introduced into the model. Large NO mixing ratios from lightning rapidly destroy ozone through the NO + O$_3$ reaction as described by Wang and Prinn [2000]. The ozone destruction resulting from including lightning NO$_x$ in the model is likely short-lived. After the cloud dissipates, much of the NO$_2$ produced by the NO + O$_3$ reaction will be photolyzed to produce NO and O($^3$P), resulting in O$_3$ production (see following section).

3.4. Chemistry-Only Model Results

The chemistry-only version of the CSCTM was used to estimate downstream ozone production in the 24 hours following the storm. Three-dimensional chemical fields at 180 minutes in the CSCTM simulation were used to initialize the chemistry-only version. For these calculations, the storm is assumed to have dissipated and clear-sky photolysis rates are used. The same 24 x 36 km sampling box shown in Figure 12a was used to analyze the results at the end of the 24 hour simulations. Table 5 gives the average mixing ratios within the sampling box at 9 km AGL for a number of species at the beginning and end of the chemistry-only simulation that included lightning NO$_x$. Ozone production averaged 1.5 ppbv day$^{-1}$ in the convective plume at this altitude, while substantial NO$_x$ conversion to HNO$_3$ took place. Decreases in HCHO and CH$_3$OOH were caused by photolysis.
The impact of lightning NOx on ozone was examined by averaging the change in ozone mixing ratios within the box for the lightning and no-lightning cases. Figure 15 shows the change in net ozone production in the 24 hours following the storm due to lightning NOx, calculated by subtracting the 24-hour change in O3 from the no-lightning simulation from the 24-hour change in O3 from the simulation with lightning NOx. On average with lightning, there is additional net O3 production maximizing at approximately 5 ppbv day\(^{-1}\) at 5.5 km. The injection of lightning NOx causes a decrease in net ozone production averaging less than 2 ppbv day\(^{-1}\) between 8 and 10.5 km. There is a maximum decrease in net O3 production exceeding 5 ppbv day\(^{-1}\) at 9 km, and maximum additional net production of approximately 9 ppbv day\(^{-1}\) at 4.5 km due to lightning. Figure 16 shows a scatter plot of lightning NOx versus the 24-hour change in net O3 production resulting from the inclusion of lightning NO in the model for the grid cells contained in the sampling box at 9 km. The general shape of the plot shows the change in net ozone production maximizing with lightning NOx mixing ratios less than 1 ppbv, then becoming less positive as lightning NOx increases. After lightning NOx mixing ratios exceed approximately 2 ppbv, lightning NOx causes decreased net ozone production in the model.

4. DISCUSSION

The estimated production per CG flash of 360 moles NO from the CSCTM for this storm is close to the value of 330 moles NO per flash from Fehr et al. [2004], with the difference due to the criteria for designating which BLIDS flashes were considered actual CG flashes in the two models. However, the assumed P\textsubscript{IC}/P\textsubscript{CG} ratio of 1.4 yields a production per IC flash of 462 moles NO which overestimates NO\(_x\) when compared to the observed pdfs and column mass of observations. The production per CG flash of 360
moles NO is less than the production estimated for the July 12 STERAO storm by DeCaria et al. [2005] of 460 moles NO per CG flash. The IC production rate of 360 moles NO per flash is in the range of 345 to 460 moles NO per IC flash estimated by DeCaria et al. [2005] on the basis of calculated column mass and the average vertical NOx profile. Assuming a global average flash rate of 44 flashes s⁻¹ [Christian et al., 2003], the lightning NOx production scenario from the EULINOX storm yields an annual global lightning NOx source of 7 Tg N yr⁻¹. Huntrieser et al. [2002] also estimated the global lightning NOx production rate in two ways. The first method involved calculating the average anvil NOx mixing ratios during EULINOX storms and multiplying by the average air flux out of the anvil and an estimate of the average number of thunderstorms occurring globally. The second method involved estimating NO production per meter flash channel length from NO spikes observed in the July 21 EULINOX storm and assuming a mean flash length and global flash rate. These methods yielded estimated global production rates of 3 and 4 Tg N yr⁻¹, respectively both of which are less than the estimate of 7 Tg N yr⁻¹ presented above. These differences could be because other EULINOX storms may have been less productive of lightning NO than the July 21 storm, or because the NO spikes analyzed from the July 21 storm may not have been representative of the lightning NO production in the storm. Our estimate of 1.25 x 10⁻² moles NO per meter flash channel length also compares favorably with other estimates of NO production per meter available in the literature. This estimate is within the range of 3.3 x 10⁻⁴ and 1.7 x 10⁻² moles NO per meter flash channel length from Stith et al. [1999] based on the July 10 STERAO storm. It is significantly larger than the value of 1.7 x 10⁻³ moles NO per meter flash channel length estimated by Skamarock et al. [2003] which included a number of short duration interferometer flashes not included in other studies.
of STERAO cases (e.g. DeCaria et al., 2005). It is also larger than the estimate of 4.5 x
\(10^3\) moles NO per meter flash length obtained by Huntrieser et al. [2002].

DeCaria et al. [2005] also examined the change in the net production of ozone
resulting from lightning NO\(_x\) in the convective plume following convection and found an
average anvil net ozone production increase maximizing at 10 ppbv day\(^{-1}\) at 9 km AGL.
Maximum increased ozone production at this level exceeded 12 ppbv day\(^{-1}\). The
simulations presented of the July 21 EULINOX storm show on average smaller changes
in net ozone production, maximizing at 5 ppbv day\(^{-1}\) at 5.5 km AGL. The maximum
increase in the net production of ozone was greater than 9 ppbv day\(^{-1}\) at 4.5 km. The
EULINOX storm contained much larger NO\(_x\) mixing ratios than the STERAO storm due
to convective transport of boundary layer pollution as well as more lightning. Assuming
a P\(_C/P_{CG}\) ratio of 1 for the STERAO storm yielded an average in-cloud NO\(_x\) mixing ratio
of only 0.9 ppbv at 9 km AGL (DeCaria et al., 2005), while the average at 9 km AGL 180
minutes into the simulation is 3.3 ppbv in the EULINOX storm. As a result, NO\(_x\) was
less efficient at O\(_3\) production in the EULINOX storm. The decrease in ozone production
seen in the simulation of the EULINOX storm itself may be accentuated due to the
changes to the lightning NO\(_x\) parameterization which attempt to simulate individual
lightning flashes and the spiky nature of NO\(_x\) observations by placing NO from a flash
into a small subset of randomly selected grid cells rather than uniformly distributing it
over a larger area of the simulated cloud (as implemented by DeCaria et al., 2005). The
higher NO\(_x\) mixing ratios cause a loss of ozone at some levels and only minimal amounts
of production of ozone at others within the storm.

Ozone production following convection has also been studied in global chemical
transport models. Park et al. [2004] used a global stretched-grid chemical transport
model (UMD-CTM) which included parameterized convection and lightning NO\textsubscript{x} production to examine the change in ozone following a convective event observed over Kansas and Oklahoma in 1985. When comparing ozone mixing ratios prior to convection with ozone mixing ratios in the day following convection, they found an enhancement in the downstream region at 9 km averaging 7 ppbv and ranging from zero to 25 ppbv. Prior to convection, O\textsubscript{3} at 9 km in the EULINOX simulation was 80.1 ppbv and after the conclusion of the 24-hour chemistry-only simulation, O\textsubscript{3} mixing ratios within the sampling box ranged from 80.9 to 97.2 ppbv (an increase of \~1 to 17 ppbv) with an average of 89.1 ppbv, an increase of 9 ppbv. The range of the increase in O\textsubscript{3} following convection calculated in the EULINOX simulation is less than the range of enhancement from Park et al. [2004]. The average increase in O\textsubscript{3} of 9 ppbv is slightly greater than the 7 ppbv average from the Park et al. [2004] study.

5. SUMMARY

The 3-D GCE cloud resolving model initialized with a single sounding was used to simulate a powerful thunderstorm observed on July 21, 1998 as part of the EULINOX field campaign. The model successfully reproduced a number of observed features of the storm including the splitting of the storm into two distinct cells, one of which developed supercell characteristics, and the other of which became multicellular. Time series of IC and CG flash rates were generated for both cells using BLIDS and interferometer data, and used in a parameterization of lightning NO production included in an offline 3-D CSCTM simulation driven by fields from the GCE simulation. This newly developed parameterization provides a means to better simulate the NO\textsubscript{x} resulting from lightning flashes in the highly electrified portion of a storm than is possible with the DeCaria et al. [2005] scheme.
Probability distribution functions were calculated for CO₂, O₃, and NOₓ from aircraft observations taken during 7 penetrations of the storm and model output. A comparison of CO₂ and O₃ pdfs showed the model adequately represented the transport of tracer species. However, the lack of sufficient observations in the upper troposphere and lower stratosphere for use as initial conditions hampered a full evaluation of the model transport. Several lightning NOₓ production scenarios were simulated and the results were compared with observations to determine which was most appropriate for the storm. The scenario in which IC and CG flashes both produce 360 moles of NO per flash compared most favorably with observations, both in terms of pdfs and column mass. This production scenario for a strong supercell over Germany is equivalent to an annual global source of 7 Tg N yr⁻¹. A second lightning NOₓ parameterization using average hourly flash lengths was employed to estimate a production per meter flash channel length of 1.25 x 10⁻² moles NO.

Many modeling studies have assumed IC flashes are significantly less productive of NO than CG flashes because they are less energetic and pass through lower pressure layers. Price et al. [1997] proposed that an IC flash typically produces 10% as much NO as a CG flash based on estimates of energy dissipation. This has been disputed by Zhang et al. [2003] who estimate that IC flashes dissipate between 50 and 100% of the energy of CG flashes using recent observational evidence and a reanalysis of the assumptions made in the Price et al. [1997] study. Though a typical IC flash might be expected to produce somewhat less NO than a typical CG flash, the differences in pressure where the two types of flashes typically occur and in energy dissipation may be effectively countered by the fact that IC flashes can have greater lengths. Dotzek et al. [2000] estimated that the average length of an IC flash was greater than the average length of a CG flash in the July
21 EULINOX supercell based on lightning and radar observations. Though IC and CG flashes on average may produce equivalent quantities of NO, our results suggest that an IC flash may be less productive of NO per meter flash channel length than a CG flash.

Assuming either the production scenario per flash or per meter flash channel length leads to a loss of ozone at all levels during the lifetime of the storm due to the resulting large NO mixing ratios. Chemical fields from 180 minutes in the CSCTM simulation were used to initialize a chemistry-only version of the model which includes diffusion but no further cloud-scale advection. The entire model domain is assumed to be translated downstream by the wind. This model was integrated forward 24 hours to estimate the effect of lightning NOx production on ozone in the day following the storm. Layer average increases in net production of ozone were found to maximize at 5 ppbv day\(^{-1}\) at 5.5 km, though grid cells (particularly at 8 to 10.5 km) with the highest concentration of lightning NO resulted in decreased net ozone production. We speculate that outflow from highly electrified storms or storms occurring over heavily polluted regions in other parts of the world (e.g. eastern U.S., east Asia, etc.) may also contain air parcels with reduced O\(_3\) production. Dilution of these convective plumes as they are advected farther downwind will result in a transition to increased O\(_3\) production. It appears that net O\(_3\) production over the first 24 hours in outflow from storms with large flash rates over polluted regions may be less than in the outflow from moderate flash rate storms over cleaner regions.

Figure 13. Mean NOₓ mixing ratios within the averaging box at the beginning of the passive model simulation (solid), and after 180 minutes with only transport simulated (dashed), and with lightning and transport simulated (dotted).
Figure 14. Change in O₃ mixing ratios due to lightning NOₓ during the lifetime of the storm. Solid line is the average (over the sampling box) and brackets indicate minimum and maximum change.

Figure 15. Change in net O₃ production due to lightning NOₓ in the 24 hours following the storm. Solid line is the average (over the sampling box) and brackets indicate minimum and maximum change.

Figure 16. Change in net O₃ production due to lightning NOₓ in the 24 hours following the storm versus lightning NOₓ at 9 km for grid cells contained in the sampling box.
