Devices based on surface plasmon filters having at least one metal-dielectric interface to support surface plasmon waves. A multi-layer-coupled surface plasmon notch filter is provided to have more than two symmetric metal-dielectric interfaces coupled with one another to produce a transmission spectral window with desired spectral profile and bandwidth. Such notch filters can form various color filtering devices for color flat panel displays.

DEVICES BASED ON SURFACE PLASMON INTERFERENCE FILTERS

This application is a continuation-in-part of the U.S. patent application Ser. No. 08/949,151, filed on Oct. 10, 1997, now U.S. Pat. No. 5,986,808. This application further claims the benefit of the U.S. Provisional Application No. 60/056,050, filed on Sep. 2, 1997, No. 60/059,247, filed on Sep. 18, 1997, and No. 60/060,733, filed on Oct. 1, 1997.

ORIGIN OF THE INVENTION

The invention described herein was made in the performance of work under a NASA contract, and is subject to the provisions of Public Law 96-517 (35 U.S.C. 202) in which the Contractor has elected to retain title.

FIELD OF THE INVENTION

The present invention relates to wavelength tunable optical filters and, more particularly, to devices based on a surface plasmon tunable filter.

BACKGROUND

An optical wavelength filter is a device that reflects or transmits light of a desired wavelength or within a certain wavelength range. For example, an interference bandpass filter selectively transmits light within a selected wavelength transmission bandwidth while absorbing light of wavelengths outside the transmission bandwidth. Such optical filtering with respect to wavelength provides a means of controlling the energy and spectral composition of light and is widely used in a variety of optical signal processing, detection, and display applications.

Excitation of surface plasmon waves at a metal-dielectric interface has been demonstrated as an efficient way of implementing a spectral filtering mechanism in response to an electrical control signal. See, for example, Wang and Simon, “Electronic Reflection with Surface Plasmon,” Opt. Quantum Electron. 25, 8925 (1993) and Wang, “Voltage-Induced Color-Selective Absorption with Surface Plasmon”, Appl. Phys. Lett. 67, pp. 2759-2761 (1995). Surface plasmon are oscillations of free electrons caused by resonant absorption of a p-polarized incident optical wave at a metal-dielectric interface when the wavelength and incident angle of the optical wave satisfy a plasmon resonance condition. More specifically, the plasmon resonance condition requires that the component of the optical wave vector along the metal-dielectric interface matches the plasmon wave vector, \( \mathbf{K}_p \).

\[
\mathbf{K}_p = \frac{2\pi}{\lambda} \sqrt{\epsilon_1 \epsilon_2} \quad (1)
\]

where, \( \lambda \) is the wavelength of the optical wave, \( \epsilon_1 \) and \( \epsilon_2 \) are the dielectric permittivity constants for the metal and the dielectric material, respectively.

At surface plasmon resonance, the energy of the incident optical wave is strongly absorbed and converted into the energy of oscillating free electrons in the metal. Therefore, the reflected optical wave is strongly attenuated or even vanishes. When the incident angle of the optical wave is fixed at a constant, the optical wavelength \( \lambda \) satisfying the plasmon resonance condition may be changed by varying the dielectric permittivity constant \( \epsilon_2 \) of the dielectric material. If the input optical wave is white light, the color of the reflected optical wave will change with \( \epsilon_2 \). This phenomenon effects a surface plasmon tunable filter in reflection mode.

Therefore, an electronically tunable filter can be formed by using an electro-optic material as the dielectric material. The voltage applied on the electro-optic material changes its index of refraction and thereby changes the wavelength for the surface plasmon resonance.

Wang and Simon disclose color display devices based on a surface plasmon filter using a liquid crystal electro-optic material. U.S. Pat. Nos. 5,451,980 and 5,570,139, which are incorporated herein by reference. The index of the refraction of the liquid crystal is changed by applying a voltage to alter the spectral composition of the reflected light.

SUMMARY

The devices disclosed herein use surface plasmon waves at metal-dielectric interfaces to alter the spectral composition of light having a p-polarized component. The metal material in general has a negative dielectric constant and the dielectric material has a positive dielectric constant. The electrical field of the p-polarized component at non-normal incidence induces electric dipoles in a metallic layer that forms one side of a metal-dielectric interface due to the excitation of the free electrons in the metal. The direction of the induced dipoles is perpendicular to the metal-dielectric interface. The radiation of the dipoles generates a surface plasmon wave with a wave vector parallel to the interface. The strength of the surface plasmon wave is maximal at the metal-dielectric interface and decays exponentially on both sides of the interface.

The energy conversion from the incident light to the surface plasmon wave is maximal when the incident angle, wavelength of the incident light, the dielectric constants of the metal and the dielectric materials satisfy a surface plasmon resonance condition. In general, this resonance condition relates to mode matching between the p-polarized incident light and the surface plasmon wave at a metal-dielectric interface and may vary with the specific incident coupling mechanism and the structure of the interfaces (e.g., a single interface or two closed coupled interfaces).

One embodiment of a surface plasmon filter includes a dielectric layer sandwiched between two metallic layers to form two closely spaced symmetrical metal-dielectric interfaces. The optical thickness of the dielectric layer is configured to allow for excitation of surface plasmon waves on both metal-dielectric interfaces by an input optical wave. The dielectric layer may be less or larger than one wavelength but in general on the order of a wavelength. The coupling between the surface plasmon waves produces a reflected wave and a transmitted wave that have mutually complimentary colors.

The surface plasmon resonance frequency can be tuned by adjusting the optical thickness of the dielectric layer. Either the layer thickness or the index of the refraction of the dielectric layer may be adjusted to change the transmission wavelength. One implementation uses an adjustable air gap as the dielectric layer. Another implementation uses a layer of an electro-optic material to vary the optical thickness by changing the index of refraction with a voltage control signal.

One or more additional metal-dielectric interfaces may be added and coupled to the two metal-dielectric interfaces to form a multilayer surface plasmon filter. Such a multilayer structure can be configured to achieve a desired shape in the transmission spectrum profile. For example, a “notch” filter
can be so formed to produce a square-like transition from a transmissive spectral region to a reflective spectral region and to achieve a desired transmissive bandwidth.

The surface plasmon filter can be used to form a wide range of devices. One such device is a tunable Fabry-Perot filter based on an air-gap surface plasmon filter. Various color filters for color display systems such as color LCD displays can be formed based on a surface plasmon filter.

These and other aspects and advantages of the present invention will become more apparent in light of the accompanying drawings, the detailed description, and the claims.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1A is a diagram showing one embodiment of the surface plasmon filter using a high-index material for light coupling.

FIG. 1B is a diagram showing another embodiment of the surface plasmon filter using a grating for light coupling.

FIG. 2 is a diagram showing a surface plasmon filter using a layer of electro-optic material and high-index prisms.

FIG. 4 is a diagram showing a surface plasmon filter using an adjustable air gap and high-index prisms.

FIG. 5 is a chart of calculated transmission spectrum of the surface plasmon filter of FIG. 4 under different spacings of the air gap.

FIG. 6 is a diagram showing a surface plasmon filter formed with two glass plates having micro-prisms arrays.

FIG. 7 is a chart of calculated transmission spectrum of the surface plasmon filter of FIG. 6 under different spacings of the air gap between the glass plates.

FIG. 8A is a block diagram showing a high-resolution spectrometer based on a Fabry-Perot filter and a surface plasmon filter.

FIG. 8B is a diagram illustrating integration of a surface plasmon filter and a sensor array.

FIG. 9 is a diagram of color LCD display based on a surface plasmon filter.

FIG. 10 is a diagram showing one embodiment of a multi-layer surface plasmon filter having six coupled metal-dielectric interfaces.

FIG. 11 shows calculated reflection spectrum of the filter of FIG. 10 with three identical liquid crystal layers of 185 nm thick, two outer silver films of 20 nm thick and two mille silver films of 40 nm thick.

FIG. 12 is a flowchart showing the design process of a multi-layer surface plasmon notch filter.

FIG. 13A are plots showing exemplary colors that can be generated by different overlapping the reflection spectra of two tunable surface plasmon filters.

FIG. 13B is a diagram showing one embodiment of a reflective flat panel color display based on the technique shown in FIG. 13A.

FIG. 13C is a diagram showing one implementation of a reflective flat panel color display of FIG. 13B.

FIG. 14A is a diagram showing one embodiment of a color filtering device for producing sequential colors.

FIG. 14B-F shows the reflectivity spectra of three filters based on a multi-layer design when illuminated by a white input beam.

FIG. 14C is a CIE diagram to show the color purity of the primary colors produced by the filters shown in FIG. 14B.

FIG. 15 is a diagram illustrating a color display system based on the filter of FIG. 14A.

FIG. 16A is a diagram showing an exemplary smart card image device based on surface plasmon filters.

FIG. 16B illustrates the manufacturing process of the smart card imaging device of FIG. 16A.

FIG. 16C is a diagram showing one design of addressing the transistors in the device of FIG. 16A.

FIGS. 17A, 17B, and 17C show structure and operation of one color filter using three surface plasmon tunable filters.

FIG. 18 shows another color filter based on the device of FIGS. 17A through 17C.

FIG. 19A shows an alternative construction of the pixel in the device of FIG. 16A, where only three layers are used to form a surface plasmon filter: a metal layer, a liquid crystal layer and a thin-film transistor layer.

FIG. 19B shows that each plate can be a simple high-index glass plate with one side formed with thin-film transistors and the other side coated with a metal layer.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

FIG. 1A shows one embodiment 100 of a coupled surface plasmon tunable filter. Two symmetrical metal-dielectric interfaces 110a and 110b are formed by sandwiching a dielectric layer 110 between two substantially identical metallic layers 120a and 120b. The metallic layers 120a and 120b are sufficiently thin so that the evanescent electromagnetic waves can penetrate the metallic layers 120a and 120b. The evanescent waves may be generated by, for example, an incident optical wave or coupling of oscillating electrical fields caused by surface plasmon waves. In general, the thickness of the metallic layers 120a and 120b may be any value. However, the preferred thickness is from about 5 nm to about 150 nm and most preferably from about 10 nm to about 100 nm. A variety of metals may be used for forming the layers 120a and 120b, including but not limited to, Ag, Al, Au, K, and Li.

The dielectric layer 110 may be any dielectric material, including air or an electro-optic material including inorganic crystals (e.g., KDP, KTP, LiNbO3), polymide guest-host materials, organic crystals (e.g., MMONS and MNA), organic salts, and liquid crystals. The thickness of the dielectric layer 110 is sufficiently thin to allow for efficient energy coupling between the first metal-dielectric interface 110a and the second metal-dielectric interface 110b. Preferably, the optical thickness of the dielectric layer 110 is on the order of a wavelength.

An incident optical wave 102 to the metallic layer 120a can excite a surface plasmon wave at the first interface 110a if the surface plasmon resonance condition is met. The energy of photons in the surface plasmon resonance is converted into collective oscillations of free electrons generated in the first metallic layer 120a. This causes strong absorption of the photons at the resonant wavelength in the incident optical wave 102 and the unabsorbed photons are reflected as the reflected wave 104 from the first metallic layer 120a.

The oscillating free electrons in the first metallic layer 120a generate an evanescent optical wave at the wavelength...
of the absorbed resonant photons. The field of the evanescent optical wave penetrates the thin dielectric layer 110 to reach the second metallic-dielectric interface 110b. The field of the evanescent optical wave can excite a second surface plasmon wave on the second interface 110b. This is at least in part due to the symmetry of the two interfaces 110a and 110b with respect to the dielectric layer 110. The second surface plasmon wave is substantially identical to the first surface plasmon wave including the frequency and the plasmon wave vector. The oscillating free electrons in the pattern of the first surface plasmon wave in the dielectric layer reflects the rest of the input light as the reflected wave 104. In particular, a white input beam may be split into a colored transmitted beam and a reflected beam which is spectrally complimentary to the transmitted beam.

The excitation of the first surface plasmon wave at the first interface 110a and the excitation of the second plasmon wave at the second interface 110b are correlated. Under a surface plasmon resonance condition, the evanescent field pattern of the first surface plasmon wave in the dielectric layer 110 and the evanescent field pattern of the second surface plasmon wave affect each other to match the field patterns. The incident angle and wavelength of the incident optical wave 102 and the optical thickness of the dielectric layer 110 can be adjusted to satisfy the resonance condition in order to achieve simultaneous excitation of both the first and the second plasmon waves. The exact resonance condition can be determined by applying the Maxwell wave equations to each of the dielectric layer 110 and the two metallic layers 120a and 120b and by matching the boundary conditions at interfaces 110a and 110b.

For a given incident angle of the input optical wave 102, the optical thickness of the dielectric layer 110 may be adjusted to achieve excitation of the surface plasmon waves at different wavelengths to affect color filtering in both transmitted beam 108 and the reflected beam 104. The optical thickness of the dielectric layer 110 is the product of its index of refraction and the layer thickness. Therefore, the layer thickness of the dielectric layer 110, or the index of refraction, or both may be varied in order to select different wavelengths to meet the resonance condition of surface plasmon waves at the interfaces 110a and 110b.

Referring to FIG. 1, the embodiment 100 further includes two identical dielectric layers 130a and 130b respectively formed on the metallic layers 120a and 120b. The index of the refraction of the layers 130a and 130b is larger than that of the dielectric layer 110 in order to properly couple the input optical beam 102 to excite surface plasmon waves. For example, a high-index prism (e.g., TiO2) may be used to couple the input optical wave 102 at a specified incident angle. In general, the incident angle of the input optical wave 102 is larger than the critical angle for total reflection defined by the high-index layer 130a (or 130b) and the dielectric layer 110.

The coupling dielectric layers 130a and 130b are usually in form of prisms and may be made of any dielectric material with an index of refraction higher than that of the dielectric layer 110. Examples of suitable high-index materials include glasses such as SF glass (e.g., SF6, SF57, SF 58, SF 59, etc.) and LaSF glass (e.g., LaSF18, LaSFN31, LaSFN9, LaSF13, etc.), crystals such as TiO2, sapphire, diamond, and high-index polymers.

Alternatively, a grating may also be used for light coupling as shown in FIG. 1B. In this embodiment, two substantially identical gratings 140a and 140b substitute the high-index coupling dielectric layers (130a and 130b). Each of the gratings 140a and 140b is coated with a layer of metal film (150a and 150b) to form the metal-dielectric interfaces. The gratings 140a and 140b are configured to produce a diffracted order 102b of the incident light 102 to have a wave vector parallel to the metal-dielectric interfaces. For example, the first-order diffraction beam may be used as the beam 102b to excite a surface plasmon wave and the zero-order diffraction beam is reflected as the beam 102a. Similar to the embodiment 100 of FIG. 1A, the coupling between the two symmetric interfaces produces the transmitted beam 106.

In the case where a surface plasmon wave is excited at only one metal-dielectric interface, the resonance condition requires

$$\frac{2\pi}{\lambda} \cdot \sin \theta \pm \frac{2\pi}{d} \cdot p = k_{ps}$$

where d is the grating period, p is an integer indicating the order of diffraction and Kps is the surface plasmon wave vector defined by Equation (1). For the coupled symmetric structure shown in FIG. 1B, the surface plasmon resonance condition is more complex than Equation (2) and can be similarly determined as in the embodiment 100 of FIG. 1A by applying the Maxwell wave equations to each of the dielectric layer 110 and the two metallic layers 150a and 150b and by matching the boundary conditions at the interfaces.

The gratings 140a and 140b may be implemented in a number of ways. For example, one way is to attach a separately-formed grating to the dielectric layer 110; another way is to directly form a coupling grating on the dielectric layer 110; yet another way is to etch a grating on the surface of the dielectric layer. The gratings 140a and 140b in first two examples are preferably made of a transparent material in the operating spectral range. A dielectric material may be used to form a support for the grating coupled filter of FIG. 1B.

One implementation of the embodiment 100 is shown in FIG. 2. A thin layer of electro-optic material 210 with a fixed thickness less than a wavelength is sandwiched between two thin metallic films 220a and 220b. A first prism 230a is used as an input light coupling element by placing the hypotenuse in contact with the first thin metallic film 220a. Symmetrically, a second prism 230b identical to the 230a is disposed on the second metallic film 220b as an output light coupling element. The index of refraction of the prisms 230a and 230b is larger than that of the electro-optic material 210. An electrical voltage supply 212 is connected to the electro-optic material 210 to provide an electrical control of its index of refraction.

The electro-optic material 210 may be any suitable electro-optic material including KDP, KTP, LiNO3 crystals or a liquid crystal material. The thin metallic films 220a and 220b may be made of silver, aluminum, or other metals with desired dispersion properties in the surface plasmon excitation. In the visible spectral range, metals such as Ag or Al may be used. In the IR range, Au and alkali metals such as...
K or Li may be used. The prisms 230a and 230b may be made of a high-index glass as previously described.

The index of refraction of the electro-optic material 210 changes in response to a voltage control signal from source 212. This index change further causes a change in the optical thickness of the electro-optic material 210. Therefore, the surface plasmon resonance frequency and the transmission spectrum of the device 200 change accordingly.

FIG. 3A is a chart showing the calculated transmission spectrum for two silver films separated by a 150-nm electro-optic material layer. The calculation is based on the Maxwell wave equations. The prisms are made of TiO₂, and the metallic films 220a and 220b are 35-nm silver films. The incident angle is fixed at 45°. When no voltage is applied, the index change dn is zero, and the peak transmission is about 62% at 450 nm (blue). When the voltage-induced index change of the electro-optic layer is dn = 0.2, the peak transmission shifts to 530 nm (green) with a transmission of about 73%. When the index increases by an amount of dn = 0.5, the peak transmission shifts to 650 nm (red) with a transmission of about 70%. Thus, all three primary colors (red, green, and blue) can be achieved in the transmitted light by changing the index of the electro-optic layer by an amount in a range of from 0 to about 0.5. The intensity and linewidth of a transmission peak in the filter 200 depend on the optical properties and the thickness of the metallic films 220a and 220b. Metals with small imaginary part of the dielectric constant usually lead to higher peak transmission and narrower bandwidth. A thinner metallic layer can be used to achieve greater peak transmission and broader bandwidth.

In addition, different operation spectral ranges may be achieved by the use of different metals for the metallic films 220a and 220b. For example, potassium films may be used to replace the silver films in the device of FIG. 2 to change the transmission spectrum from the visible range to the infrared (IR) range. FIG. 3B shows that potassium films each of 900 Å are used to achieve a tunable IR spectral range from 1050 nm to 1700 range by varying the index of the electro-optic layer 210 by an amount in a range of from 0 to about 0.5, i.e., index varies from about 1.5 to about 2.0. The coupling prisms are made of TiO₂ and the incident angle is about 45°. This particular IR range covers the transmission windows near 1.3 μm and 1.5 μm for fiber communication systems.

Another implementation of the embodiment 100 is shown in FIG. 4 which replaces the electro-optic material 210 of FIG. 2 with an adjustable air gap 410 between the two prisms 230a and 230b. In this configuration, the metallic films 220a and 220b are respectively formed by placing the glass plates 610 and 620 which may be any photodetector array including a CCD array, a diode array, a phototransistor array or an active pixel sensing array (“APS”). In operation, the surface plasmon filter 600 may be replaced by a layer of electro-optic material with a fixed thickness. The surface plasmon resonant frequency can be altered by electrically changing the index of refraction.

The above-described surface plasmon tunable filters may combine with a Fabry-Perot filter to form a high-resolution spectrometer as shown in FIG. 8A. Fabry-Perot filters can be made to have a high finesse number to achieve high spectral resolution. However, the tuning range of many Fabry-Perot filters is limited. The spectrometer of FIG. 8A has an advantage of the high resolution of the Fabry-Perot to filter and the wide tunable range of the surface plasmon filter.

FIG. 8B shows another device based on the surface plasmon filter. This device combines the micro-prism surface plasmon filter 810 with a sensor array 820. The micro-prism surface plasmon filter 810 has an active layer 812 which can be either an air gap or a layer of electro-optic material between two metallic films. The sensor array 820 may be any photodetector array including a CCD array, a diode array, a phototransistor array or an active pixel sensing array (“APS”). In operation, the surface plasmon filter 810 selects the transmission spectrum and the sensor array 820 measures the intensity of the incident pattern, respectively. As shown in FIG. 8A, a Fabry-Perot filter may be added to the device of FIG. 8B to enhance the spectral resolution.

In addition, the device of FIG. 8B may be integrated on a single chip to form an image spectrometer-on-a-chip. In particular, an APS array may be used as the sensor array and the active layer 812 of the surface plasmon filter may be divided into many pixels to match the pixel size of the APS array. The pixel of the active layer 812 can be addressed by an active matrix and the spectrum of each pixel can be individually adjusted.
Furthermore, a surface plasmon filter can be used in either a projection or a direct-view color display system. FIG. 9 shows a back-lit color liquid crystal display (“LCD”) system 900 based on a prism-coupled surface plasmon filter 930. A light source 910 and a lens system 920 produce a white beam 922 with a substantially homogenous illumination profile. The light source 910 may be a lamp with a line-shaped filament and the lens system 920 may simply be a cylindrical lens. The surface plasmon filter 930 receives the white beam 922 and produces a beam 924. The color of the beam 924 is electrically controlled by the filter 930 using either an adjustable air gap or an electro-optic material. A reflector 940 further guides the filtered beam 924 to a monochromatic LCD panel 950. Preferably, the reflective surface of the reflector 940 has structures to make the reflected light diffusive in order to improve the homogeneity of the images.

The filter 930 is configured to operate in the visible spectral range from about 400 nm to about 750 nm. For example, the prisms may be made of TiO₂ and the metallic films may be made of silver. In addition, an electro-optic material with an index variation range of about 0.5 may be used to achieve all three additive primary colors (i.e., red, green, and blue). FIG. 3A shows one possible spectral output of such a filter.

The filter 930 and the LCD panel 950 are controlled by a display control circuit 960. The filter 930 performs color filtering in the homogeneous illumination beam 924 and the LCD panel 950 modulates the intensity distribution of the beam 924 to form images. During each frame scanning in the LCD panel 950 (e.g., 60 frames per second), the control circuit 960 controls the filter 930 to change the color of the beam 924 three times by sequentially hopping through three primary colors. This process produces colored images. In many LCD color displays, three pixels are used to produce one image pixel and each pixel has a color filter to produce one of the three primary colors. Thus, the LCD display 900 of FIG. 9 eliminates the color filter in each pixel can be improved by increasing the number of layers.

The above surface plasmon filters having two coupled metal-dielectric interfaces usually produce narrow bandwidth in either reflection or transmission with a Gaussian-like spectral profile. In certain applications, a broad band filter is desirable.

For example, many display systems use a white light source to generate desired primary colors by color filtering. If the bandwidth of the color filters is very narrow, only a small fraction of energy near the desired primary color wavelengths is used and the rest is rejected. Although this may produce highly pure primary colors, the light utilization efficiency is low. For certain display applications that require high display brightness and low power consumption (e.g., portable computers), broadband color filters may be preferred.

A notch filter is an example of such a filter which has a relatively flat center transmission or reflection region and sharp cut-off edges. Four, six or more metal-dielectric interfaces may be coupled to form a multi-layer surface plasmon filter to achieve a "notch" spectral profile in transmission or reflection.

FIG. 10 shows one embodiment 1000 of a multi-layer surface plasmon filter having six metal-dielectric interfaces. Four metal films 1010a, 1010b, 1010c, and 1010d and three dielectric layers 1020a, 1020b, 1020c are alternatively stacked relative to one another to form six symmetric metal-dielectric interfaces. The metal films are sufficiently thin so that the evanescent electromagnetic waves can penetrate therethrough. The dielectric layers are also thin and have an optical thickness on the order of a wavelength.

As an example, the dielectric layers may be formed of an electro-optic material such as a liquid crystal. A voltage may be applied to the two outer metal films 1010a and 1010d to change the optical thickness of each of the three dielectric layers 1020a, 1020b, and 1020c. In this configuration, the device effects three capacitors connected in series. The electric fields in the dielectric layers are essentially the same. The applied voltage changes the index of refraction of each dielectric layer and thereby the optical thickness. This changes the transmission wavelength.

FIG. 11 shows calculated reflection spectrum of the filter 1000 having three identical liquid crystal layers of 185 nm thick, silver films 1010a and 1010d of 20 nm thick and silver films 1010b and 1010c of 40 nm thick. Reflection curve 1 represents the reflection spectrum for transmitting in blue-green region when no voltage is applied across the silver films 1010a and 1010d. When a voltage is applied to increase the optical thickness of each dielectric layer, the transmission window shifts toward a longer wavelength. Curves 2, 3, 4, and 5 respectively represent reflection spectra for an voltage-induced increase in the index for 0.1, 0.2, 0.3, and 0.4.

Comparing to the transmission profiles of surface plasmon filters having two coupled metal-dielectric interfaces (e.g., FIGS. 3A and 3B), the spectral profile of the multi-layer filter 1000 has a wider bandwidth and a relatively flat region in the central colored images. Such performance can be achieved by properly configuring the dielectric layers and the metal films. In general, the flatness of the “valley” in the reflection spectrum or “peak” in the transmission spectrum can be improved by increasing the number of layers.

FIG. 12 is a flowchart showing the design process of a multi-layer surface plasmon notch filter. If a desired reflection or transmission profile is not achieved by modifying the thickness values of the dielectric layers and the metal layers, the number of layers may be further modified.

The tunable notch filter 1000 in FIG. 10 can be used to form a reflective flat panel display. Consider a color filtering device having two tunable notch filters F1 and F2 used in combination in reflection mode as shown in FIG. 13A. Each notch filter is configured to transmit a bandwidth that covers about two thirds of the visible spectrum. A unpolarized white beam can be polarized by using a polarizer so that the input beam to the first filter F1 is p-polarized. The first filter F1 filters the p-polarized input beam to produce a first reflected beam at a first wavelength determined by the voltage applied thereto. The second filter F2, disposed relative to the first filter to receive the first reflected beam as a p-polarized input, filters the first reflected beam to produce a second reflected beam. The reflections from these two notch filters F1 and F2 can be combined to produce any visible color and grey scale by controlling the applied voltages to shift the reflection spectral regions relative to each other.

Several examples for generating different colors and grey scales by using the above color filter device are illustrated in FIG. 13A. In the first chart in FIG. 13A, the notch filter F1 is tuned to transmit light from 400 nm to 600 nm and reflect red and other wavelengths while the notch filter F2 is tuned to transmit the IR spectrum and to reflect all visible light. This produces red light by reflecting a white beam off the notch filters F1 and F2. Different red grey scales can be
generated by shifting the filters F1 and F2 to partially overlap with each other with different degrees in the red region. For example, shifting the filter F2 toward the visible region while maintaining the filter F1 at the spectral position shown would reduce the brightness of the red. When the F2 is at a position to transmit green and red and reflect other colors, the reflection becomes black (no reflected light). If the transmission windows are completely shifted out of the visible region, the reflection is white.

The second and third charts in FIG. 13A show generation of green and blue colors, respectively, in the reflected light by using the two notch filters F1 and F2. The fourth chart in FIG. 13A shows a dark green color by partially overlapping the transmission windows in the green-yellow region (approximately from 500 nm to 600 nm).

The multi-layer surface plasmon filter 1000 shown in FIG. 10 can be used to form reflective flat panel color display. FIG. 13B depicts one embodiment. A prism array is formed of two layers of micro prisms 1310a and 1310b of a high-index optical material (e.g., plastic) that stack over each other and is used to provide proper optical coupling. The interface sections 1320 between two layers of micro prisms are tuned with multi-layered metal films and electro-optic dielectric layers as shown in FIG. 10. Each interface section is applied with a control voltage so that the reflected wavelength can be independently controlled. A polarizing layer 1330 is formed on top of the prism array to select p-polarized light. The angle of the micro prisms is configured in such a way that a visible light beam incident in a normal direction to the prism array surface satisfies the surface plasmon resonance condition. In a preferred embodiment, the prism angle is near or at 45° as shown.

Two adjacent interface sections define one color pixel 1340. An incident ray 1350 is reflected by the two interface sections to exhibit a desired color and grey scale when their transmission windows are tuned at proper spectral positions. FIG. 13C shows one example of actual color display device based on the embodiment shown in FIG. 13B. A microlens array 1360 is disposed between the polarization layer 1330 and the microparticles to increase the viewing angle. Each microlens in the array 1360 is located to cover one color pixel. An opaque mask 1370 with an array of apertures can be placed at or near the focal plane of the microlenses array 1360. The apertures are aligned with the pixels. In operation, light incident on each pixel is collimated by the respective microlenses and then reflected twice in that pixel to obtain color and grey scale, and finally is spread to a divergent beam by the same microlenses to form a large viewing angle. A slant incident ray 1380, for example, is refracted by a corresponding microlens and is reflected back to another direction as a ray 1382.

The reflective flat panel color displays in FIGS. 13B and 13C can use ambient light for illumination. Reflecting light at a wavelength satisfying the resonance condition of the surface plasmon filter can be nearly completely reflected to achieve a high efficiency.

Such reflective color displays provide an alternative to the conventional color LCD displays widely used in notebook computers and other portable devices. A color LCD display such as the active matrix LCD in a notebook computer consumes a large portion of the power supply (e.g., as high as 80%). Use of the surface plasmon reflective display can significantly reduce power consumption and extend the actual operating time of a portable device such as a notebook computer when powered by a battery.

Another application of the surface plasmon filters is to form a tunable color filtering device to produce sequential colors for projectors using white light sources for illumination.

FIG. 14A shows one embodiment 1400 of such a tunable color filtering device. Three surface plasmon filters 1410, 1420, and 1430 are arranged relative to one another to sequentially reflect an incident white beam 1440 from the first filter 1410 to the second filter 1420 and to the third filter 1430. The first and third filters 1410 and 1430 are placed in a plane 1404 and are displaced from each other. The second filter 1420 is placed to face the plane 1404 in a position to reflect light from the first filter 1410 to the third filter 1430. A high-index optical material 1402 is filled between the filters 1410, 1420, and 1430 to provide proper optical coupling similar to the high-index prisms used in above surface plasmon filters. Since p-polarized light is needed to excite surface plasmon waves in each filter, a polarizer can be placed in the input path of filter 1410 to ensure that only p-polarized light enters the device 1400.

For a given filter, if the transmission window is set for a selected color, the reflection of a white incident light is the complementary color of that selected color. Each filter can be configured to satisfy a surface plasmon resonance to transmit a selected primary color when no voltage is applied. In addition, a proper voltage can be applied to the filter to destroy the resonance condition so that wavelengths from 400 nm to 700 nm are completely reflected in the entire visible spectrum. Hence, each filter can be configured to have two states: an “on” state to transmit a selected primary color and reflect other colors when no voltage is applied, and an “off” state when a voltage is applied to reflect all visible colors.

A notch surface plasmon filter as shown in FIG. 10 can be used for this multiple layers of alternating metal films and dielectric layers can be configured to have a transmission window at a primary color (e.g., red, green, or blue) with a bandwidth of about one third of the visible spectrum without an external voltage. A voltage can be used to shift the transmission window out of the visible spectrum to generate the “off” state so the filter behaves like a mirror. Referring to FIG. 14A, the three filters 1410, 1420, and 1430 can be designed to transmit red, green, and blue when no voltage is applied, respectively. Therefore, when a white light beam is sent in and no voltage is applied to any of the filters, the red portion is lost by reflection at the first filter 1410, the green portion is lost by reflection at the second filter 1420, and the blue portion is lost by reflection at the third filter 1430. Hence, no light comes out. This produces a “black” color. To produce a color, a proper voltage is applied to each of the filters to turn “off” the transmission of each filter so that all filters become reflective, like mirrors. The transmitted colored light in each filter can be absorbed by using a light absorbing material. For example, a semiconductor substrate can be used to function as both a light absorber and a heat dissipator. An additional heat absorber may be used to further extract the heat from the light absorbing material.

An output with a primary color can be produced, therefore, by applying voltages only to two of the filters and applying no voltage to the remaining filter. The output color, therefore, is the primary color of the filter without voltage. A sequence of three primary colors can be generated by sequentially turning on and off voltages on the filters. For example, a red output can be produced by applying voltage to the first filter 1410 to turn off the transmission in the visible range while applying no voltage to the filters 1420 and 1430. When a voltage is applied to the second filter 1420 and no voltage is applied to the filters 1410 and 1430, the output is green. A blue output can be generated by applying voltage only to the third filter 1430.

This allows for a full color display. The switching rate for each filter should be at least three times of the frame rate, e.g., 180 Hz for a 60-Hz frame rate.
A spatial light modulator can be combined with the filtering device 1400 in FIG. 14A to modulate the intensity of the filtered output and to produce color images. FIG. 15 shows one embodiment 1500 of such a full-color display system. A spatial light modulator 1560 such as a LCD panel is implemented. Since the colors are sequentially produced, there is no need to use three adjacent pixels in the light modulator 1560 to produce a color pixel. Each pixel forms a color pixel. This increases the image resolution. A white light source such as a lamp 1510 is used for illumination. A suitable reflector 1520 is used to direct and collimate the light. An optical relay element 1530 (e.g., a lens) couples the light from the reflector 120 to the color filters 1410, 1420, and 1430. An optical integrator 1540 is used to improve the uniformity of the intensity across the beam. A polarizer 1550 ensures the light incident to the filters is p-polarized. A projection lens 1570 is used to project the output color images to a screen for viewing in either front projection mode or back projection mode.

The device shown in FIG. 14A may be modified to form a special flat panel display, a “smart card” image device having an array of active pixels each capable of producing colors and intensity modulation. FIG. 16A shows an exemplary smart card image device 1600 having an input surface 1610 and an output surface 1612. Each pixel 1620 is formed of a high-index dielectric material such as a high-index glass 1630 to form a light-conducting channel to guide light from the input surface 1610 to the output surface 1612. The light-conducting channel has two parallel surfaces 1640 and 1650. The surface 1640 is coated with either a dielectric material with an index less than that of the dielectric material 1630 to confine light within the channel by total internal reflection or a reflective coating (e.g., metal) is generally in the forward direction. The complementary colors cyan, magenta, and yellow of the primary additive colors red, green, and blue are respectively produced. The incident white beam has a half cone angle of about 6.7° and a contrast ratio up to greater than 200:1 can be obtained with a liquid crystal material as the electro-optic material in the multi-layer construction. FIG. 14C is a CIE diagram to show the color purity of the primary colors produced by the filters shown in FIG. 14B. The color triangle formed by heavy lines represents colors that can be produced by the surface plasmon device. The colors that can be produced by a 27” CRT are indicated by a color triangle of light lines for comparison. The natural colors are also shown.

Such a color filtering device can be used to replace a color wheel and simplifies the display structure. In the embodiment 1600, an incident light beam is reflected six times within the light conducting channel, three times by the surface 1640 and three times by the filters 1660, before exiting the output surface 1612. The intensity (i.e., grey scale) and color (i.e., spectral composition) of the output light beam are determined by the spectral positions of the three transmission windows of the filters. Similar to the filtering operations by successive reflections from two multi-layer surface plasmon filters shown in FIG. 13A, the relative spectral positions of the three transmission windows determine the color of the output beam and the amount of the overlap of the transmission windows produces different grey scales. At least two filters are needed in each light conducting channel to provide full color and intensity modulation. In general, increasing the number of filters in each conducting channel can increase the number of grey scales and the colors.

The above smart card device uses the surface plasmon filters to form color images without color separation and color fusing. Only one projection is needed to image the output beams from the output surface to a screen. This provides an efficient display with a simple structure. Such smart card device requires addressing a TFT array in a three dimensional space since at least two TFTs required in the direction perpendicular to the card surface. For a smart card with VGA resolution, at least 480x640x2 TFTs need to be addressed. FIG. 16C shows one design for addressing the TFTs. The connection of the row lines are straight and can be done with known techniques. The column lines are formed by thin metal strips that run through the output surface 1612. Such thin metal strips do not significantly affect the efficiency since the scattered light from the strips is generally in the forward direction. One application of the such smart card device is the direct-view flat panel display by placing a screen at the output surface. The stack structure of the smart card device eliminate many limitations in the direct-view LCD displays such as the glass flatness and the liquid crystal layer uniformity. Hence, large-size direct-view flat panel displays exceeding 30” can be made using such technology.

Sequential light filters, such as color wheels and the device shown in FIG. 14A, transmit one color at a time. Hence, about two thirds of the energy of an input white beam is lost. Such loss of light energy can be avoided by combining three surface plasmon tunable filters to form a color generating device 1700 as shown in FIG. 17A. Three prism-coupled surface plasmon tunable filters 1710, 1720, and 1730 are displaced from one another to...
generate three primary output colors from a white input beam 1702. Two reflectors 1740 and 1750 such as prisms are respectively placed between the filters 1710 and 1720 and between the filters 1720 and 1730 to direct the reflected beam from the filter 1710 to the filter 1720 and the reflected beam from the filter 1720 to the reflector 1730. Preferably, each filter is a multi-layer surface plasmon filter as shown in FIG. 10 and has a tunable transmission window with a bandwidth about one third of the visible spectral range.

In operation, the three filters 1710, 1720, and 1730 are applied with different voltages to respectively transmit at three different primary colors. When the white input beam 1702 is p-polarized, the first primary color component is transmitted as a first transmitted beam 1702a at the first filter 1710 and the remaining is reflected and directed to the second filter 1720 as a p-polarized beam 1702b. The second filter 1720 transmits the second primary component as beam 1703a and reflects the rest to the third filter 1730 as beam 1703b. The beam 1703b is essentially comprised of the third primary component and is transmitted through the third filter 1730 as beam 1704a to produce the third primary color.

Hence, at any moment, the device 1700 produces three different primary colors. Each image frame has three fields with different colors. To produce color images, the voltage on each filter is scrolled to sequentially produce three different primary colors at a rate three times of the frame rate. Thus, in a single frame, each of the three primary colors is scrolled through all three filters once. FIGS. 17A, 17B, and 17C show one cycle of such color scrolling in a frame.

Similar to the color display system shown in FIG. 15, a spatial light modulator such as a LCD panel only needs one pixel to produce all three colors. This eliminates the need for expensive miniaturized color filters and the requirement of using three pixels to form one color pixel in many conventional LCD displays. Hence, using the device in FIG. 17 can improve image resolution, simplify device structure, and reduce manufacturing cost. Since all colors are used, the efficiency of such device is increased by a factor of 3 over many conventional LCD color displays.

All visible light in the p-polarized input is utilized in the device 1700. However, if the input white beam 1702 is unpolarized like in many lamp sources, only the p-polarized portion in the visible range is used for image display and the such filters provides easy construction of many of the above devices.

For another example, although all the embodiments disclosed change either the thickness or the index of refraction of the center dielectric layer to tune the transmission wavelength, the incident angle of the input light may also be adjusted to change the surface plasmon resonance condition, thereby changing the transmission wavelength. The incident angle may be changed with an angle adjustment device by either adjusting the direction of the input beam or adjusting the orientation of the surface plasmon filter relative to the input beam. In implementation of such angular tuning scheme, the index of refraction and the spacing between the two metal-dielectric interfaces may be adjusted to tune the transmission wavelength.

In various color filtering and display applications, coupled multilayer surface plasmon filters such as the one in FIG. 10 are used to take the advantages of the square-like notch transmission window and the configurable transmission bandwidth obtained from proper configurations of the multiple metal-dielectric layers. However, the non-coupled absorbing surface plasmon filters having a single metal-dielectric layer as disclosed in the incorporated U.S. Pat. Nos. 5,570,139 and 5,451,980 can also be used. Although configuring the metal layer by combining different metal films can only offer limited flexibility in changing the absorption spectral profile, the simplicity in the structure of such filters provides easy construction of many of the above devices.

For example, if the surface plasmon filters in the devices of FIG. 13 are implemented by non-coupled surface plasmon filters, there is no need to eliminate the unwanted transmitted light since. In forming the device 1600, each pixel 1620 can be significantly simplified by using such non-coupled surface plasmon filters. FIG. 19A shows such an alternative construction of the pixel 1620. Only three layers are needed to form each filter: a metal layer 1650, a liquid crystal layer 1690 and the TFT layer 1670. This simplifies the manufacturing of each plate for forming the stack. FIG. 19B shows that each plate can be a simple high-index glass plate with one side faced with TFI's and the other side coated with a metal layer. Such plates are spaced by spacers when forming the stack so that the liquid crystal can be filled in the space provided by the spacers after slicing.

These and other variations and modifications are intended to be encompassed by the appended claims.

What is claimed is:

1. An optical device, comprising:
   a first array of prisms formed of a transparent material, each prism having at least a first prism facet and a
second prism facet intersecting said first prism facet at a prism apex;

at least one metal layer and an electro-optical dielectric layer contacting each other to form a metal-dielectric interface on each prism facet, wherein said dielectric layer has a refractive index less than a refractive index of said first and second arrays of prisms, and wherein said metal-dielectric interface generates a surface plasmon wave in response to a p-polarized input light beam to transmit light at a selected wavelength within a bandwidth according to a control voltage from said metal-dielectric interface and a second surface opposing said first surface;

a second array of prisms substantially identical to said first array, disposed to engage to said first array in such a way that each prism facet in said second array conformably contacts said metal-dielectric interface formed on a respective prism facet of said first array, wherein said second array couples an input light beam to said metal-dielectric interface and the said first and second arrays are configured so that said input light beam is respectively reflected once by metal-dielectric interfaces on two adjacent prism facets of said first array to produce a desired color and a desired grey scale.

2. The device as in claim 1, further comprising a polarization layer disposed relative to said second array.

3. The device as in claim 2, further comprising a lens array disposed between said polarization layer and said second array, wherein each lens in said lens array is positioned over two adjacent prism facets of two different prisms in said first array.

4. A device, comprising,

a first tunable optical filter disposed to receive an input light beam to produce a first reflected beam and configured to include at least one metal layer and one electro-optical dielectric layer which form a metal-dielectric interface to generate a surface plasmon wave in response to a p-polarized input beam to transmit light at a first selected wavelength within a first bandwidth according to a first control voltage and to reflect light at other wavelengths;

a second tunable optical filter disposed relative to said first tunable optical filter to receive said first reflected light beam, said second tunable optical filter having at least one metal layer and one electro-optical dielectric layer to form a metal-dielectric interface that generates a surface plasmon wave in response to a p-polarized input beam to transmit light at a second selected wavelength within a second bandwidth according to a second control voltage and to reflect light at other wavelengths,

wherein said second optical filter reflects said first reflected light beam to produce a second reflected light beam with a selected color different than a color of said input light beam, and

wherein each of said first and second tunable optical filters comprises:

- a first coupling element having a first coupling surface and operable to couple a p-polarized input electromagnetic wave to have a propagation component parallel to said first coupling surface;
- a first metallic film formed on said first coupling surface and operable to produce free electron oscillations in response to excitation of said p-polarized input electromagnetic wave, wherein said first metallic film is configured to allow penetration of evanescent fields;
- a first dielectric layer having a first surface in direct contact with said first metallic film to form a first metal-dielectric interface and a second surface opposing said first surface;
- a second metallic film substantially identical to said first metallic film and formed on said second surface of said first dielectric layer to form a second metal-dielectric interface that is substantially symmetric to said first metal-dielectric interface with respect to said first dielectric layer;
- a second dielectric layer having a first surface in direct contact with said second metallic film to form a second metal-dielectric interface and a second surface opposing said first surface;
- a third metallic film substantially identical to said second and first metallic films and formed on said second surface of said second dielectric layer to form a fourth metal-dielectric interface that is substantially symmetric to said third metal-dielectric interface with respect to said second dielectric layer; and
- a second light coupling element configured to have a second coupling surface which is in direct contact with said third metallic film and operable to couple an electromagnetic wave propagating in said third metallic film along said second coupling surface into an output electromagnetic wave,

wherein said first, second, third, and fourth metal-dielectric interfaces are operable to support surface plasmon waves and to transfer energy of a selected spectral component in said p-polarized input electromagnetic wave from said first coupling surface to said second coupling surface by coupling a selected surface plasmon mode on said first metal-dielectric interface to said fourth metal-dielectric interface.

5. The device as in claim 4, wherein said first and second dielectric layers are formed of an electro-optic material and said first and third metallic films are applied with different voltages to change an optical thickness of said dielectric layers to tune a center wavelength of said selected spectral component.

6. The device as in claim 4, wherein said first and second dielectric layers have a thickness on the order of about one wavelength of said input electromagnetic wave.

7. The device as in claim 4, wherein said first and second coupling elements comprise prisms which are made of a dielectric material having a dielectric constant higher than a dielectric constant of said first and second dielectric layers.

8. The device as in claim 4, further comprising a spatial light modulator positioned to receive said second reflected beam from said second optical filter, said spatial light modulator having an array of light-modulating pixels to modulate said second reflected beam to produce an image.

9. The device as in claim 8, wherein said spatial light modulator includes a liquid crystal panel.

10. The device as in claim 4, further comprising an optical integrator positioned in an optical path of said input light beam to increase uniformity of a spatial intensity distribution of said input light beam.
