Non-invasive measuring devices responsive to changes in a patient's intracranial pressure (ICP) can be accurately calibrated for monitoring purposes by providing known changes in ICP by non-invasive methods, such as placing the patient on a tilting bed and calculating a change in ICP from the tilt angle and the length of the patient's cerebrospinal column, or by placing a pressurized skull cap on the patient and measuring the inflation pressure. Absolute values for the patient's pressure-volume index (PVI) and the steady state ICP can then be determined by inducing two known changes in the volume of cerebrospinal fluid while recording the corresponding changes in ICP by means of the calibrated measuring device. The two pairs of data for pressure change and volume change are entered into an equation developed from an equation describing the relationship between ICP and cerebrospinal fluid volume. PVI and steady state ICP can then be determined by solving the equation. Methods for inducing known changes in cerebrospinal fluid volume are described.
1. Field of the Invention

This invention relates in general to measuring/monitoring of intracranial pressure and pressure volume index in human patients, and more specifically to a non-invasive method for monitoring intracranial pressure and changes in intracranial pressure.

2. Description of the Related Art

Monitoring of intracranial pressure and pressure volume index is of significant diagnostic and post-operative importance for patients with cranial injuries, pathologies, or other conditions, that may affect the pressure of the subarachnoidal fluid around the brain, and for patients who have undergone brain surgery.

Intracranial pressure is regularly measured and monitored by means of a pressure sensor inserted through the skull into the brain. Usually a hole is drilled in the skull, and a catheter with a pressure sensor is inserted into the brain fluid. To obtain a pressure volume index, the change in intracranial pressure is monitored after a known bolus of saline solution is inserted into the cerebrospinal fluid, or after a saline solution is inserted at a known rate. This known procedure, while simple and accurate, is not suitable for long term monitoring, because an open wound must be maintained in the skull for the catheter with the pressure sensor. Antibiotics are only partially effective in treating cranial infections, so the pressure sensor can only be left in situ for two weeks or less.

Long term monitoring of intracranial pressure, without the need for maintaining an open wound in the skull, is possible if a pressure sensor with a transmitter is implanted into the brain. The intracranial pressure is thereafter monitored by means of a receiver located outside the skull. Such a solution however, is unattractive because of risks involved in implanting anything in the brain, and because of the problems of providing power to an implanted transmitter. One such remote pressure sensor is described in U.S. Pat. No. 4,124,023 to Fleischmann et al. However, this device uses nuclear material as an energy source, making it poorly suited for implantation into a human brain.

Other methods, claiming to be non-invasive methods suitable for monitoring of intracranial pressure, are based on the measurement of some quantity that depends on intracranial pressure, but which does not have a fixed relationship to intracranial pressure.

One such method is described in U.S. Pat. No. 4,204,547 to Allocca. Allocca occludes the blood flow in a jugular vein for a few seconds, and measures the resulting rate of change of blood flow within the jugular vein upstream of the occlusion as an indicator of the intracranial pressure.

Another such method, proposed in U.S. Pat. No. 4,564,022 to Bosenfeld et al., directs a sensory stimulus towards the patient, e.g. a flash of light into the eyes, and measures the latency of a resulting negative-going wave of electrical brain activity as an indicator of intracranial pressure.

These known indirect methods may be used, under very restricted conditions, as possible indicators of variations of the intracranial pressure in a patient. However, absolute values for the intracranial pressure cannot be obtained directly as there is no predetermined fixed ratio between the observed signals, obtained by these known non-invasive monitoring methods, and the absolute value of the intracranial pressure. Such calibration is possible by inserting a pressure sensor into the brain of the patient being monitored, however, this is a traumatic and undesirable procedure.

SUMMARY OF THE INVENTION

Accordingly, it is the object of the present invention to provide a non-invasive method for measurement of absolute values of intracranial pressure and pressure volume index in a human patient.

It is another object of the present invention to provide a non-invasive method for long term monitoring of both intracranial pressure and the pressure volume index in a human patient.

It is a further object of the present invention to provide a non-invasive method for calibrating indirect measurements of intracranial pressure to obtain absolute values for intracranial pressure.

It is a still further object of this invention to provide a means to monitor changes in intracranial pressure in a human patient.

These and other objects of the invention are achieved by a method for non-invasive measurement of intracranial pressure and pressure volume index, which comprises the steps of: providing a non-invasive measuring device responsive to intracranial pressure, calibrating said measuring device by introducing known changes in intracranial pressure and recording the pressure changes by the measuring device, inducing known changes in the volume of the cerebrospinal fluid while measuring the corresponding changes in intracranial pressure by means of said calibrated measuring device, obtaining two sets of corresponding values for change in volume (\(AV\)) and change in intracranial pressure (\(AP\)), entering each of the two sets of values for \(AV\) and \(\Delta p\) into equation

\[
\Delta p = P_0 (10^{\frac{AV}{PoPVI}} - 1)
\]

and solving said set of two equations for PVI and Po to obtain accurate values for the pressure volume index PVI and the intracranial pressure Po for the patient.

BRIEF DESCRIPTION OF THE DRAWINGS

These and other objects of the present invention will be understood from the description herein, with reference to the accompanying drawings, in which:

FIG. 1A is a side view of a patient with sensing devices attached to forehead and neck lying in supine position on a horizontal hospital bed;

FIG. 1B is a side view of a patient with sensing devices attached to forehead and neck lying in supine position on a tilted hospital bed;
FIG. 2 is a perspective view of a seated patient with a sensing device attached to the forehead and fitted with a pressurized skull cap;

FIG. 3 is a perspective view of a patient with a sensing device attached to the forehead lying on the side;

FIG. 4 is a block diagram of a preferred measuring device for use with the invention.

DETAILED DESCRIPTION OF A PREFERRED EMBODIMENT

The human brain and the spinal cord are immersed in a fluid called the cerebrospinal fluid. The cerebrospinal fluid (cSF) is contained in a membrane covering the inside of blood vessels, which are in direct communication with the equation (4) in a truncated power series, collecting terms, device attached to the forehead lying on the side;

Pressurized skull cap;

Fluid called the cerebrospinal fluid. The cerebrospinal fluid PVI, or by using the "SOLVE' function in modem scientific calculators.

for use with the invention.

Equations (3a) and (3b) are obtained by solving the simultaneous equations (3a) and (3b) by known methods. Examples of methods for solving this set of equations are given below.

By taking the ratio of equations (3a) and (3b), equation (4) is obtained:

\[
\frac{\Delta P_1}{\Delta P_2} = \frac{10^{PVI_{\text{PV}+1}} - 1}{10^{PVI_{\text{PV}+1}} - 1}
\]

A quite accurate value for PVI is obtained by inserting into equation (4) data from the measurement of two pairs of corresponding values for \(\Delta V\) and \(\Delta P\) and fitting a computer generated algorithm of equation (4) to the data by varying PVI, or by using the "SOLVE' function in modern scientific calculators.

An approximate, but quite accurate, value for PVI may also be obtained by expanding the exponential functions in the numerator and the denominator of the right hand side of equation (4) in a truncated power series, collecting terms, and solving the resulting equation for PVI. If the first three terms in the power series is kept, equation (5) for PVI is obtained:

\[
PVI = \frac{\Delta P_1}{\Delta P_2} (\Delta V_2)^2 - (\Delta V_1)^2
\]

If the first four terms in the power series is kept, the more accurate, but still approximate, equation (6) for PVI is obtained:

\[
PVI = \frac{\Delta P_1}{\Delta P_2} (\Delta V_2)^2 - (\Delta V_1)^2 + \frac{24}{25} \frac{\Delta P_1}{\Delta P_2} (\Delta V_2)^3 (\Delta V_1) + 15 \left( \frac{\Delta P_1}{\Delta P_2} (\Delta V_2)^4 - 15 (\Delta V_1)^4 \right)
\]

Once PVI is obtained, \(P_0\) can be calculated from either of equations (3a) or (3b) by inserting the correct value for PVI.

Another way to calculate \(P_0\) from a single measured pair of \(\Delta P\) and \(\Delta V\) when PVI has been determined may also be obtained by taking the derivative of equation (1) to get equation (7):

\[
\frac{dP}{dV} = \frac{P_0}{0.434(PVI)}
\]

For small variations in \(P\) and \(V\), \(dP\) and \(dV\) can be replaced by \(\Delta P\) and \(\Delta V\), respectively, and the resulting equation solved to get an approximate, but quite accurate equation (8) for \(P_0\):

\[
P_0 = 0.434(PVI) \frac{\Delta P}{\Delta V}
\]

Measurements of \(\Delta P\) and \(\Delta V\) can be obtained by non-invasive methods. Two preferred methods, but by no means the only methods, to measure \(\Delta P\) and \(\Delta V\) for the determination of intracranial pressure and pressure-volume index will be described below.

It is commonly assumed that the skull of an adult is so rigid that the skull volume is constant. It is therefore...
assumed that changes in csf volume (ΔV) involve mainly compression of the spongy brain tissue. Comprehensive tests have shown that this assumption is incorrect. The skulls of adults actually expand and contract like balloons with changes in ICP, and this expansion and contraction of the skull accounts for almost all of the volume changes in the csf caused by variations in the ICP.

Any measurement system or device sufficiently sensitive to respond to appropriate anatomical configuration changes caused by pressure changes can accordingly be used to measure changes in ICP. A preferred device for measuring small variations in skull size in response to variations in ICP is the constant frequency pulsed phase-locked-loop (CFPPLL) ultrasonic measurement device described by Yost and Cantrell, and also described in a paper entitled "Constant frequency pulsed phase-locked loop instrument for measurement of ultrasonic velocity" by Yosi, Cantrell and Kushnick, published in Rev. Sci. Instrum. 62 (10) October 1991. The CFPPLL measurement device applied to measuring or monitoring intracranial pressure will be described below with reference to FIG. 4.

The signal from the ultrasonic CFPPLL device depends on the diameter of the cranium and is not a direct measure of the intracranial pressure. This is true for all measurement devices based on mechanical deformation of the skull or related structures, as well as all other known non-invasive measurement devices responsive to intracranial pressure variations. The signal from such non-invasive measurement devices thus can not be used for measurements or monitoring of absolute ICP variations unless a calibration as will be described herein has first been performed.

A. Methods to measure ΔP
1. Tilt angle method.

FIGS. 1A and 1B show a patient lying supine on a hospital bed. An ultrasonic transducer mounted on the front of the skull above the nose and approximately 1 cm below the hairline is connected via a cable to an electronic apparatus. The measuring device provides a measurement of small variations in the diameter of the skull. When the bed is tilted as shown, the intracranial pressure will increase. Measuring device provides a measurement of a change in skull dimension in response to a change in intracranial pressure. If the distance from the center of the skull to the sacrum is L, as indicated in FIGS. 1A and 1B, the increase in pressure will be as given in equation (9):

\[ ΔP = \rho g L \sin φ \]  

where:
- \( ΔP \) = Pressure change
- \( \rho \) = Mass density of the spinal fluid
- \( g \) = Gravitational constant
- \( L \) = Distance
- \( φ \) = Tilt angle for patient

By using various tilt angles \( φ \), the various changes in intracranial pressure (ICP) can be calculated from equation (9). These calculated changes in ICP can be used to calibrate the output from the measuring device, or any other appropriate measuring device sufficiently sensitive to respond to appropriate anatomical configuration changes caused by changes in intracranial pressure.

2. Pressurized skull cap method.

FIG. 2 illustrates another method of calibration, which uses a helmet containing an inflatable skull cap, in which a known pressure is applied to the cranial vault by means of a hose, a pump, a valve, and a manometer. Calibration is accomplished by correlating the output of a measuring device with a transducer mounted on the front of the skull with the applied pressure in the skull cap. The accuracy of this method depends on the design of the skull cap and may differ from the accuracy of the tilt-angle method outlined above.

B. Methods to vary and measure ΔV:

1. Bolus Injection method.

FIG. 3 shows a patient, whose cerebrospinal axis is in the supine position, but where the patient is rotated onto the patient’s side. The patient has an ultrasonic transducer placed against the skull directly above the nose and approximately one centimeter below the hair line. This transducer is connected via a cable to an electronic apparatus for measurement of small variations in diameter of the skull.

Between appropriate vertebrae, or at an other appropriate access point, a measured bolus of saline or other appropriate solution is injected by a syringe into the cerebrospinal system. Let the volume of a first injection be \( ΔV_1 \). By assuming that the injection of this bolus is given at the clinically recommended and appropriate injection rate, it will give rise to a peak change in intracranial pressure \( ΔP_1 \). This pressure change \( ΔP_1 \) is measured by readings from the measuring device, which has previously been calibrated by the tilt angle method or the pressurized skull cap method, and is recorded along with the corresponding bolus injection volume \( ΔV_1 \).

After allowing time for the intracranial pressure ICP to equilibrate to its steady state value following the first bolus injection, a second bolus injection of volume \( ΔV_2 \) is given, and the resulting peak change in intracranial pressure \( ΔP_2 \) is measured.

The two measured pairs of values of ΔV and ΔP are then inserted into equations (3a) and (3b), and the patient’s pressure-volume index PVI and the intra-cranial pressure \( P_{ci} \) is calculated by solving the two simultaneous equations by one of the methods described above in connection with equations (4)-(8).

2. Blood Flow Method:

Another method for measurement of ΔV is based on measurement of changes in blood flow to the brain, as indicated in FIG. 1A.

A patient resting in supine position on a horizontal hospital bed has an ultrasonic transducer placed against the front of the skull. The transducer is connected via a cable to an electronic apparatus for accurate measurement of small variations in diameter of the skull.

The measuring device has previously been calibrated by the tilt angle method or the pressurized skull cap method described above to provide accurate readings of variations in the intracranial pressure.

The patient also has an ultrasonic blood flow transducer mounted on the neck. The blood flow transducer is connected via a cable to an ultrasonic A-scan instrument. By
using the determined vein diameter together with the velocity profile from the blood flow meter. An instantaneous blood volume change can be determined. Devices for measurement of blood flow and blood vessel diameter are well known in the art, and will not be discussed in detail herein.

Theoretically, net blood flow into or out of the brain would require measurement of the blood flow in all veins as well as in all arteries that service blood flow out of and into the cerebral system. In most cases it is, however, possible to model the total blood flow from measurement of blood flow in one vein. With this in mind, we measure (1) the diameter of the vein, and (2) the velocity profile of the venous flow. We calculate a blood volume flow rate in a manner known to those skilled in the art.

The change in the blood volume flow rate is measured at a temporary occlusion of an artery or a vein. One can then calculate a first change in blood volume $\Delta V_1$, which is recorded together with the corresponding change $\Delta P_1$ in ICP, as measured by the previously calibrated pressure responsive measuring device. A second pair of data, $\Delta V_2$ and $\Delta P_2$, is obtained by occluding a different vein or artery. The two pairs of data are inserted into equations (3a) and (3b), and $P_1$ and $P_2$ are then calculated by solving the two equations, e.g., as described above with reference to equations (4)-(8).

After the patient’s pressure-volume index PVI and steady state intracranial pressure $P_{10}$ has been determined, the calibrated measuring device, or any other calibrated measurement device responsive to changes in intracranial pressure, can be used to monitor changes in ICP directly and continuously.

FIG. 4 is a block diagram for a Constant Frequency Pulsed Phase-Locked-Loop (CFPPLL) ultrasonic measurement device, which is a preferred measurement device for use as part of the invention.

The CFPPLL measurement system uses properties of an ultrasonic wave propagating along a path defined by the ultrasonic beam and bound by the skull-meninges-dura complex, or appropriate substructures within this complex, and the measured change in the phase of the propagating ultrasonic wave due to the change in the wave propagation path length accompanying a change in ICP is used as a measure of variations in ICP. The CFPPLL measuring device is preferred because it provides very high sensitivity and excellent repeatability and long term stability, and is a block diagram for a CFPPLL measuring device.

The CFPPLL measuring device includes an ultrasonic transducer, which is shown mounted on the front of the skull of a patient under monitoring. The transducer is via cable supplied with variable width acoustic tonebursts from an electronic apparatus, which includes a constant frequency synthesizer followed by a power splitter, a gate, which determines the width of the acoustic toneburst, a power amplifier, and a coupling/decoupling network.

Acoustic signals reflected from the far side of the skull are received by the transducer and channelled via the cable, the coupling/decoupling network, and a preamplifier to a first input of a phase detector. A second input of the phase detector receives a second signal from the synthesizer via a power splitter, a buffer, a voltage controlled phase shift network, and a readout for the measuring device.

The output from the phase detector is fed via a sample-and-hold circuit to an integrator, and from the integrator via a normally closed phase shift control switch to an adder circuit, which also receives a phase set point voltage from a phase set point potentiometer as an echo of the original pulse. Any changes in the propagation conditions, such as path length changes, produce associated phase changes in path 1. These phase changes are the information sought in measurement.

Path 2, which is a reference path, includes a voltage controlled phase shift network, whose output is used for phase comparison with the signal from the measurement path. The phase detector detects the relative phase difference between the signals in the two paths, and generates an output signal proportional to the cosine of the phase difference. The control voltage to the voltage controlled phase shift network is automatically changed until the output voltage of the phase detector is zero, which occurs when the two signals are in quadrature. The control voltage to the voltage controlled phase shift network comes through a buffer from the power splitter.

The buffer provides matching of the electrical input impedance to that of the phase shift network. The phase shift is controlled by a dc voltage applied to a control input of the voltage controlled phase shift network. The output of the voltage controlled phase shift network passes through a calibrated line stretcher, used for calibration of the system, and a buffer to the phase detector. During data collection the setting of the calibrated line stretcher is not changed.

Phase comparison of the two paths is performed by the phase detector, which is a product detector combined with a low pass filter. The phase detector output voltage can be written as one-half the product of the input voltage amplitudes times the cosine of the phase difference between the two signals. The output of the phase detector is passed both to the sample-and-hold circuit, which selects the desired portion of the phase signal, and to an output port through a buffer for observation on an oscilloscope (not shown). The portion of the phase signal chosen for measurement is selected by an adjustable timing pulse to the sample and hold circuit, whose output is passed to an integrator.
A method for non-invasive measurement of intracranial pressure and pressure volume index in a patient, comprising the steps of:

(a) calibrating a measuring device by introducing known changes in intracranial pressure and reading the corresponding pressure changes with the measuring device;

(b) inducing known changes in the volume of the cerebrospinal fluid while measuring the corresponding changes in intracranial pressure with the calibrated measuring device;

(c) obtaining two sets of corresponding values for change in volume and change in intracranial pressure and change in intracranial pressure for the patient based on the values for change in volume and change in intracranial pressure;

(d) obtaining values for the pressure volume index and the intracranial pressure for the patient based on the values for change in volume and change in intracranial pressure.

2. A method for non-invasive measurement of intracranial pressure and pressure volume index according to claim 1, wherein said measuring device is an ultrasonic transducer applied to the skull of the patient.

3. A method for non-invasive measurement of intracranial pressure and pressure volume index according to claim 1, wherein said known change in intracranial pressure is induced by placing the patient on a tiltable bed and calculating said change in intracranial pressure from the length of the patient’s cerebrospinal system and the tilt angle of the bed.

4. A method for non-invasive measurement of intracranial pressure and pressure volume index according to claim 1, wherein said known change in intracranial pressure is induced by placing an inflatable cap to a known pressure.

5. A method for non-invasive measurement of intracranial pressure and pressure volume index according to claim 1, wherein said known changes in the volume of the cerebrospinal fluid are induced by injecting boluses of fluid into the spinal cord of the patient.
6. A method for non-invasive measurement of intracranial pressure and pressure volume index according to claim 1, wherein known changes in the volume of the cerebrospinal fluid are induced by temporary obstruction of veins or arteries in the patient's neck while the blood flow into or out of the brain is measured.

7. A method for non-invasive measurement of intracranial pressure and pressure volume index according to claim 1, wherein the step (d) comprises:

obtaining values for the pressure volume index and the intracranial pressure for the patient based on the values for change in volume and change in intracranial pressure using the equation

\[ \Delta P = P_0 \left( 10^{\frac{\Delta V}{PV}_I} - 1 \right) \]

where \( \Delta P \) is the change in intracranial pressure and \( \Delta V \) is the change in volume obtained in step (c).

8. A method for calibrating a device for monitoring changes in intracranial pressure in a patient comprising the steps of:

(a) applying a measuring device to the patient to provide output signals in response to changes in intracranial pressure;

(b) inducing a known change in intracranial pressure by placing the patient on a tiltable bed and calculating said known change in intracranial pressure from the length of the patient's cerebrospinal system and the tilt angle of the bed; and

(c) recording an output signal from said measuring device corresponding to said known change in intracranial pressure.
