Abstract.

A case of long-range transport of a biomass burning plume from Alaska to Europe is analyzed using a Lagrangian approach. This plume was sampled several times in the free troposphere over North America, the North Atlantic and Europe by 3 different aircraft during the IGAC Lagrangian 2K4 experiment which was part of the ICARTT/ITOP measurement intensive in summer 2004. Measurements in the plume showed enhanced values of CO, VOCs and NO$_y$, mainly in form of PAN. Observed O$_3$ levels increased by 17 ppbv over 5 days. A photochemical trajectory model, CiTTyCAT, is used to examine processes responsible for the chemical evolution of the plume. The model was initialized with upwind data, and compared with downwind measurements. The influence of high aerosol loading on photolysis rates in the plume is investigated using in-situ aerosol measurements in the plume and lidar retrievals of optical depth as input into a photolysis code (Fast-J), run in the model. Significant impacts on photochemistry are found with a decrease of 18% in O$_3$ production and 24% in O$_3$ destruction over 5 days when
including aerosols. The plume is found to be chemically active with large O_3 increases attributed primarily to PAN decomposition during descent of the plume towards Europe. The predicted O_3 changes are very dependent on temperature changes during transport, and also, on water vapor levels in the lower troposphere which can lead to O_3 destruction. Simulation of mixing/dilution was necessary to reproduce observed pollutants level in the plume. Mixing was simulated using background concentrations from measurements in air masses in close proximity to the plume, and mixing timescales (averaging 6.25 days) were derived from CO changes. Observed and simulated O_3/CO correlations in the plume are also compared in order to evaluate the photochemistry in the model. Observed slopes changed from negative to positive over 5 days. This change, which can be attributed largely to photochemistry, is well reproduced by multiple model runs even if slope values are slightly underestimated suggesting small underestimation of photochemical processes. The possible impact of this biomass burning plume on O_3 levels in the Europe boundary layer is also examined by running the model for a further 5 days, and comparing with data collected at surface sites, such as Jungfraujoch, which showed small O_3 increases and elevated CO levels. The model predicts significant changes in O_3 over this 10 days due to photochemistry but the signal is largely lost due to the effects of dilution. However, measurement in several others BB plumes over Europe show that O_3 impact of Alaskan fires can be punctually significant over Europe.
1. Introduction

There is a large body of evidence that pollutants can be transported from source regions to remote areas, and thus can influence the oxidizing capacity over downwind regions, and occasionally regional air quality thousands kilometers away from emissions. During export from emission regions, polluted plumes undergo chemical evolution and mixing with air masses of different origin so that their chemical composition can radically change. Ozone levels in such polluted plumes are of particular interest since O$_3$ is a major pollutant, damaging for health but also the major source of the OH radical, and the most efficient cleansing agent in the atmosphere. O$_3$ is mainly produced by reactions involving oxidation of volatile organic compounds (VOCs), and carbon monoxide (CO) in the presence of nitrogen oxides (NO$_x$=NO+NO$_2$), and mainly destroyed by reactions involving H$_2$O and HO$_x$ radicals.

O$_3$ evolution in anthropogenic pollution plumes transported over long distances has been widely studied [Wild and Akimoto, 2001; Jacob et al., 1999] but less is known about O$_3$ formation in biomass burning plumes, especially those in boreal regions. Biomass burning (BB) has been recognized as an important source of many trace gases and particles [Crutzen et al., 1979; Crutzen and Andreae, 1990] including CO, CO$_2$, CH$_4$, VOCs, oxygenated organic compounds and NO$_x$. BB emissions occur most extensively in tropical and subtropical regions with the largest contributions from Africa and South America, and smaller contribution from southeast Asia, Indonesia and Australia [Galenter et al., 2000]. Boreal forest fires in North America and Russia are less frequent, but important in summer time in certain years [Stohl et al., 2006]. Long-range transport of BB
plumes has been previously observed during several campaigns. For example, African BB plumes were sampled over the tropical south Atlantic [Andreae et al., 1994] and over Australia [Pak et al., 2003], southeast Asian BB plumes were sampled over the west Pacific [Kondo et al., 2004] whilst Canadian BB plumes have been sampled over Tennessee (United States) [Wotawa and Trainer, 2000; McKeen et al., 2002] and also at the surface station Mace Head (Ireland) [Forster et al., 2001]. All these plumes showed enhanced CO correlated with enhanced O$_3$. Modeling studies of BB plumes (either with box models or global models) also often show net O$_3$ production in such plumes [Mauzerall et al., 1998; Duncan et al., 2003; Tang et al., 2003].

The IGAC Lagrangian 2K4 experiment was conducted in summer 2004 over the North Atlantic as part of ICARTT [Fehsenfeld et al., 2006], also encompassing the European Intercontinental Transport of Ozone and Precursors (ITOP) experiment. The aim of this experiment was to perform a Lagrangian study of polluted air masses, making interceptions several times using 4 different research aircraft during their transport from North America to Europe. Lagrangian experiments have been conducted previously, for example, in the stratosphere [Rex et al., 1998] using balloons measurements, or close to emissions regions [Daum et al., 2000; Volz-Thomas and Kolahgar, 2000]. This is the first time that a Lagrangian experiment has been conducted in the free troposphere on intercontinental scales. The main advantage of this kind of study is that the exact chemical change in a plume over several days can be estimated by comparing two Lagrangian samplings, and the processes leading to these changes can be evaluated with reduced uncertainty in the initial chemical composition of the plume. After the campaign a detailed analysis using trajectories, a Lagrangian dispersion model, and in-situ measurements was performed.
by Methven et al. [2006], and showed that several Lagrangian samplings of the same air masses had indeed been achieved. The period of the campaign was characterized by extensive fires in Alaska (the largest on record), and northern Canada [Damoah et al., 2006; Stohl et al., 2006]. The quantity of CO released during this period is believed to be of the same order as anthropogenic emissions from the entire continental United States for the same period [Pfister et al., 2005; Turquety et al., 2006]. CO enhancements due to these fires were observed together with aerosols, and trace gas enhancement in the Arctic [Stohl et al., 2006], in North America, both in the boundary layer (BL) and the free troposphere (FT) over Chebogue Point (Nova Scotia) [Duck et al., 2006], and Texas [Morris et al., 2006], in the lower free troposphere over the Atlantic Ocean [ValMartin et al., 2006], and in the FT over Europe [Petzold et al., 2006; Ravetta et al., 2006]. Deep convection associated with these fires (so-called pyroconvection) may have also led to injection of BB plumes into the upper troposphere (UT), and even into the lower stratosphere (LS) [Damoah et al., 2006].

In the study reported here, we focus on one particular case of the transport of a BB plume over the North Atlantic that was sampled by 3 different aircraft over a period of 5 days (section 2). To evaluate the relative contributions of chemical and dynamical processes to the evolution of O_3 concentrations in the plume during transport, a photochemical trajectory model has been used (section 3). BB plumes are also characterized by high aerosol loadings, and therefore, the model was improved to include the effects of BB aerosols on photolysis rates by making use of measured parameters to estimate aerosol optical properties (section 4). This is the first time, to our knowledge, that measured parameters have been used to constrain photolysis rate calculations over intercontinen-
tal distances. In section 5, results are presented from model runs initialized with upwind data, and compared to downwind measurements. The model was run along one trajectory representative of the plume transport pathway, and which gave the match between plume samplings. The model was run first with chemistry only, and then including mixing with air masses in close proximity to the plume. The ability of the model to reproduce the contribution of photochemistry to O$_3$ changes in the plume, was further tested in section 6, by examining the evolution of O$_3$/CO correlations. Model runs initialized with measurements taken across the plume sampling were compared to downwind O$_3$;CO ratios. Finally, we examine other available data collected downwind over Europe in order to see if a signal of this BB event could be detected. Further model runs were used to estimate the overall change in O$_3$ concentrations since the upwind sampling 10 days earlier (section 7). Whilst the results presented here are for one particular event, such detailed Lagrangian analyzes are very valuable since they allow direct evaluation of processes occurring in a plume during long-range transport.

2. Lagrangian Forest Fire Plume Case

Methven et al. [2006] used a novel technique to identify Lagrangian matches between flight segments from different aircraft during the entire IGAC Lagrangian 2K4 campaign. This technique combined Lagrangian trajectories from the United Kingdom Global Atmospheric Modeling Project (UGAMP) model using global meteorological ERA-40 analyzes, hydrocarbon fingerprint analysis, and results from a particle dispersion model (FLEX-PART). A match was defined as an occasion when a pair of whole air samples collected during different flights exhibited highly correlated hydrocarbon fingerprints (when such measurements were available), and the sample-time windows were also connected by both
backward and forward trajectories. Results from FLEXPART run with CO tracers were also used to confirm matches. Five clear Lagrangian cases covering a variety of situations, such as low and upper level export of pollutants from North America, and long-range transport of BB plumes from Alaska and Canada over the North Atlantic to Europe were identified. An important consideration is whether instrument errors can lead to observed differences between samplings. Intercomparison flights between the different aircraft showed good agreements for O$_3$, and differences of a few ppbv for CO. Further details, as well as a critical evaluation of this Lagrangian technique, can be found in Methven et al. [2006].

In this paper, we focus on one of these Lagrangian cases, the case of long-range transport of an intense BB plume sampled over 5 days first by the National Aeronautics and Space Administration (NASA) DC8 over Newfoundland on 18 July, then by the U.K. Facility for Airborne Atmospheric Measurements (FAAM) BAe146 flying out of the Azores on 20 July, and lastly the German Deutsches Zentrum für Luft- und Raumfahrt (DLR) Falcon flying west of Paris on 23 July. The British and German aircraft were flying as part of the European ITOP project. The segments of the three flights identified as Lagrangian matches were labeled as Lagrangian case 2 by Methven et al. [2006].

Backward trajectories from the match segments of the 3 flights clearly show that the sampled plume had an origin in northern Canada and Alaska (see Fig. 1) where forest fires were burning during this period [Pfister et al., 2005]. The FLEXPART model, run with daily CO forest fire emissions from Canada/Alaska, showed that BB plumes observed during the campaign were usually an accumulation of biomass burning emissions over several days which were then transported into the free troposphere either by frontal
uplift or convection [Stohl et al., 2006]. In this case, FLEXPART results show that the pollutants sampled by the aircraft were primarily emitted by fires on the 14 and 15 July (see FLEXPART products at http://www.al.ncoa.gov/icartt_analysis/).

In this study, a photochemical trajectory model has been used to analyze observed O$_3$ changes. Therefore, it was necessary to select a trajectory representative of the plume pathway between the upwind DC8 segment (used to initialize the runs), passing via the BAe146 match, and ending at the Falcon match. Trajectories from the FLEXTRA model [Stohl et al., 1995] were used here, but it should noted that differences between trajectories from this model, and those calculated by Methven et al. [2006] are small since they used the same wind fields (European Centre for Medium-range Weather Forecast (ECMWF) ERA 40 analyzes), and for this particular case, the models produce the same features.

As noted previously, Methven et al. [2006] used a combination of forward, and backward trajectories, trace gas and VOC analysis, and FLEXPART results to match up plume segments. Use of trajectories alone shows some differences. For example, forward trajectories from the DC8 flight segment arrive around 1km lower than the Falcon match segment. Specific humidity, taken from ECMWF, is also a factor of 2 wetter. Conversely, backward trajectories from the Falcon segment are about 1km above the DC8 match, and the analysis temperature slightly colder. Errors of this nature are inherent in trajectory calculations [Stohl, 1998] gave positioning errors on the order of 20% of the travel distances). Runs along both backward and forward trajectories, and also examination of the sensitivity of O$_3$ change to temperature and water vapor (see Section 5.2) led us to use a backward trajectory from the Falcon plume match segment which gave the best agreement with observed meteorological variables.
The chemical evolution of the plume can be investigated first by examining the differences in the chemical data averaged over the time match windows (see Table 1 and Table 1 in Methven et al. [2006]). Pollutant levels measured by the DC8 were representative of the chemical composition of the BB plume 3 to 4 days after emission. By this time, CO values measured by the DC8, at a mean altitude of 7.5 km, were still exceptionally high with a mean value of 449 ppbv, and maximum values up to 600 ppbv (see Fig. 2) which correlated with high values of several hydrocarbons such as ethene, ethane and acetylene. NO\textsubscript{y} was mainly in the form of PAN with relatively low levels of HNO\textsubscript{3} and NO\textsubscript{x} observed in the plume. Unfortunately PAN was only measured at the beginning of the plume sampling (plume edge) by the DC8, and so is not representative of the mean plume value which are likely to have been higher in the plume center.

O\textsubscript{3} levels in the plume were rather low (mean value of 62 ppbv) compared to values outside the plume. However, Pfister et al. [2006] simulated background O\textsubscript{3} levels lower than 40 ppbv over the Alaskan source region during summer 2004 with a global model. Very low background (non-fire affected) values (20 to 30 ppbv) have also been measured previously in this region during ABLE-3A, so that the mean value of 62 ppbv observed 4 days later by the DC8 may indicate that O\textsubscript{3} production has in fact taken place although in-situ measurements in the emission region would be needed to confirm this. Interestingly, O\textsubscript{3} and CO were anti-correlated in the DC8 plume (see section 6 for further discussion).

By the time the BAe146 sampled the plume 2 days later, CO had decreased by about 30 ppbv, and by the time it was sampled by the DLR Falcon southwest of Paris, 3 days later, CO had decreased to half the levels seen by the DC8. In contrast, O\textsubscript{3} levels had increased by 17 ppbv over 5 days between the different samplings. In this study, we aim
to explain this O$_3$ increase. It is also interesting to examine whether a plume like this with elevated O$_3$ can have an impact on O$_3$ levels in the lower troposphere or boundary layer over Europe. This is investigated in section 7.

3. Modeling tools

The Cambridge Tropospheric Trajectory model of Chemistry And Transport (CiTTyCAT) was used to examine the different processes influencing the evolution of trace gases within the plume during transport, and in particular the evolution of O$_3$ and CO. CiTTyCAT was initialized with measured values in the upwind plume on 18 July, and run along the trajectory representative of the plume pathway. Results from the model were then compared with downwind measurements taken in the matching flight segments of the BAe146 and Falcon flights, 2 and 5 days later. In order to take into account the influence of BB aerosols on photolysis rates, the CiTTyCAT model was coupled with the Fast-J photolysis scheme [Wild et al., 2000] which can calculate photolysis rates in the presence of aerosols.

3.1. Photochemistry trajectory model: CiTTyCAT

CiTTyCAT has been previously used to examine the origin of polluted layers over the North Atlantic during previous campaigns [Wild et al., 1996; Evans et al., 2000]. The model is considered as an isolated air parcel, and run along trajectories calculated using large-scale meteorological analyzes. Eighty-eight chemical species are treated in the model including degradation of 12 hydrocarbons using chemical rate data from JPL (2003), and updates discussed in Arnold et al. [2006]. The photolysis scheme normally used in the model is based on a 2-stream multiple scattering scheme [Hough, 1988]. Emissions and
Dry deposition can be included in the boundary layer as well as wet deposition in presence of clouds. A scheme for mixing with other air masses can also be included. As discussed previously, the model was run along a trajectory calculated by the FLEXTRA model using ECMWF windfields. Temperature and water vapor used in the chemical scheme were also interpolated from the large-scale ECMWF analyzes along the trajectory. In this study, the possible effects of heterogeneous reactions on BB aerosol have not been taken into account. At present, the impacts of such reactions on this kind of aerosol, consisting primarily of organics, is very uncertain. Whalley et al. [2006], who also examined this case, attempted to take this into account by including the loss of $N_2O_5$ on BB aerosol with a $\gamma$ of 0.02 as suggested by work from Evans and Jacob [2005]. They found a 20% reduction in NO$_x$ concentrations over the first 24 hours which resulted in negligible O$_3$ changes compared to runs without heterogeneous loss. Wet deposition processes are not considered here as aerosol measurements on board the Falcon as well as ECMWF analyzed cloud fields suggest that the plume did not pass through any clouds.

Table 1 gives the mean plus/minus the standard deviation of all the measurements collected by the aircraft used in the model initialization (DC8 data - except PAN) and comparison (BAe146 and DLR Falcon data). The total number of measurements used to calculate these values in the match segments is also given. As explained in section 2, measurements were missing during the main part of the DC8 match so the measured PAN/CO correlation during the BAe146 match was used to estimate initial PAN values. This correlation was scaled by measured DC8 CO as also discussed in Whalley et al. [2006] giving a mean PAN value of 2800 pptv together with a 400 pptv standard deviation. This assumes that PAN and CO do not change much chemically between the two matches.
Indeed, as will be seen in section 5.2, simulated CO and PAN only decrease, due to chemistry, by 20 ppbv and 200 pptv, respectively, producing only a small impact on the PAN/CO correlation.

3.2. Photolysis scheme: Fast-J

The Fast-J scheme calculates photolysis rates (j-values) in the presence of prescribed cloud and aerosol layers [Wild et al., 2000] making it possible to simulate directly the physical properties of scattering and absorbing particles including the full, untruncated scattering phase function and the total optical depth. For the case under investigation, aerosol optical properties (AOPs) were derived from Falcon measurements in the BB plume. BB optical depths (ODs) used in the code were calculated from a combination of DC8 and Falcon retrievals for the 18 and 23 July as discussed in the next section. The original 2-stream photolysis scheme in CiTTyCAT uses 171 wavelengths intervals in the short-wave whereas Fast-J solves the 8-stream multiple scattering problem by using only 7 wavelength bins selected in the range 289-850 nm to minimize errors in key j-values over a range of atmospheric conditions. Values of \( j_{\text{NO}_2} \) and \( j_{\text{O}_3} \) (i.e. that producing \( \text{O}^1\text{D} \)) calculated using the two codes run in CiTTyCAT with no clouds or aerosols, were comparable to within 1%. In runs with no aerosols or clouds discussed in the following sections, a simple profile of absorbing black carbon uniformly distributed from the surface to 10 km with an optical depth of 0.001 was included to represent relatively clean conditions.

4. Aerosol measurements and optical properties

BB aerosols consist mainly of black carbon (BC), organic carbon (OC) and potassium. It is the BC component which acts as a strong light absorbent. Sampling obtained during
the campaign in a BB layer on board the BAe146 showed that these aerosols were principally made of organic and black carbon with the organic fraction dominating (Coe, pers. comm.). In the plume considered here, analysis by Petzold et al. [2006] suggests a BC fraction of 3.8% by volume compared to typical BC mass fractions in temperate/boreal fires on the order of 2 to 7% [Reid et al., 2004].

Previous studies have shown that BB aerosols can significantly decrease photolysis rates, and thereby influence O\textsubscript{3} evolution in BB plumes [Tang et al., 2003; Trentmann et al., 2003; Duncan et al., 2003]. However, their impact depends strongly on AOPs and aerosol concentration. BB aerosol AOPs can vary significantly depending on the age of the aerosols, the mode of combustion of the fire (smoldering or flaming), the combustion efficiency, and the combustible material [Reid et al., 2005]. Optical properties of BB aerosols which are wavelength dependent or their absorption properties can be very different from one fire to another. For example, aerosols from temperate and boreal fires often have higher values of the single scattering albedo than aerosols from tropical fires. Indeed, a realistic evaluation of the influence of BB aerosols on photolysis rates requires a good evaluation of the AOPs from particular fire events.

In-situ measurements of BB aerosol characteristics have been used previously to simulate aerosol impacts on photolysis rates, and thus on photochemistry, in the initial stages of plume transport during the first few hours since a fire [Trentmann et al., 2002]. To our knowledge, this is the first time that a combination of in-situ, and also airborne/ground-based lidar measurements have been used to estimate the time evolution of AOPs over several days, and their subsequent impact on photolysis rates and photochemistry during long-range transport.
4.1. Calculation of Aerosol Optical Properties

During the campaign, the DLR Falcon aircraft was equipped with extensive in-situ aerosol instrumentation. The data has been used to derive particle size distributions, particle number densities, and particle absorption coefficients. More information on the aerosol measurements can be found in Petzold et al. [2006]. Aerosol measurements in the BB plume on the 23 July were used to derive the refractive index, and size distribution of the BB aerosols following the procedure described in Fiebig et al. [2002]. This information was then used as input in a Mie code to derive BB AOPs [Mishchenko et al., 1999].

Firstly, a composite size distribution in the plume was derived from the measurements, and a three-modal lognormal distribution was fitted to the particle size distribution (see Figure 9 in Petzold et al. [2006]). Each of these three modes were parameterized by integral particle number concentration, N, particle median radius, \( r_m \), and the geometric standard deviation, sigma (\( \sigma_g \)), as given in Table 2.

For the refractive index calculation, an internal mixture of ammonium sulfate and soot was used with a soot fraction of 3.8%. As noted previously, a large fraction of the aerosol likely consisted of organic carbon, but here ammonium sulfate is used as a surrogate since it has similar refractive index [Sloane, 1984]. The soot fraction of 3.8% was derived from the measurements [Petzold et al., 2006] so that the calculated absorption coefficient matched the measurements as closely as possible and the hypothesis of internal mixture was also confirmed by the measurements. Finally, the calculated refractive index using these hypotheses was of 1.54 +0.0168i.

With these assumptions about the aerosol size distributions, and the refractive index, the extinction efficiency (Q), the single scattering albedo (\( w_0 \)), and the first 8 terms of
the Legendre expansion of the scattering phase function \( w^i, i=0,7 \) were calculated for 3 wavelengths characteristic of ultraviolet (UV) and visible wavelengths (300, 400 and 600 nm) using a Mie code. These results were directly used in the Fast-J code to simulate BB aerosol optical properties and are summarized in Table 3. In the selected BB plume, \( w_0 \), which represents the fraction of scattering versus light absorption by aerosols, is in the upper range of previous estimates derived from measurements in aged boreal and North American fire plumes (0.85 to 0.91 over wavelengths from 400 to 700 nm) [Reid et al., 2005].

4.2. Calculation of Aerosol Optical Depth

AOPs alone are not sufficient to describe the effect of a BB plume on photolysis rates. Information about aerosol concentrations, and their vertical distribution are also required. This information is given by the optical depth (OD) of the aerosol layer which corresponds to the integration of the extinction coefficient over a layer. During long-range transport of an aerosol layer, the OD changes with time as the layer becomes dispersed. Here, two ODs were derived from in-situ measurements of the DC8 aerosol lidar on the 18 July and from DLR Falcon on the 23 July [Petzold et al., 2006]. On the 18 July an OD of 0.2 at 1024 nm and 0.3 to 0.4 at 550 nm was evaluated for the BB layer with an estimated vertical dimension of 7 km which corresponded to a strong increase in the backscatter signal from the DC8 lidar (see Fig. 3). For the 23 July, a layer thickness of 2 km was used to calculate the aerosol optical depth at 550 nm using an average aerosol absorption coefficient of \( 6.5 \times 10^{-6} \text{ m}^{-1} \), and a single-scattering albedo of 0.9 at 550 nm. The height of the layer was taken from vertical profile data collected by the Falcon spanning 3.5 to 5.5 km. The aerosol absorption coefficient was determined from PSAP (Particle Soot
Absorption Photometer) data assuming that the layer-averaged value of the absorption coefficient corresponds to 75% of the peak value inside this layer which was \( 9 \times 10^{-6} \text{ m}^{-1} \) [Petzold et al., 2006]. These values yield an aerosol optical depth of 0.13 for the BB layer probed by the Falcon on 23 July.

In addition, a dual wavelength depolarization aerosol lidar operated by the SIRTA Observatory in Palaiseau [Haeffelin et al., 2005], southwest of Paris at about the same location as the Falcon measurements, reported approximately 1 hour before the Falcon sampling, a layer extending from 2.5 to 5.5 km with high aerosol loading. The lidar data was analyzed using a multi-test algorithm applied to all the lidar channels. The layer consisted of a lower layer between 2.5 and 4.0 km characteristic of BB aerosols (1064/532-nm color ratio of about 0.25 and 2% depolarization), and an upper layer between 4.0 and 5.5 km containing larger particles (0.5 color ratio). No measurements were available later on this day, but it is likely that this BB layer was part of the same BB layer observed by the Falcon. An optical depth of 0.1 to 0.15 was estimated for the entire layer based on the lidar power attenuation between the observed lidar return above the aerosol layer, and the theoretical molecular lidar return in the absence of aerosols [Cadet et al., 2005]. This confirms that, even if the Falcon may not have sampled the entire vertical distribution of the BB plume, the Falcon profile was representative of the main vertical extent of this aerosol layer.

4.3. Photolysis scheme evaluation

In order to evaluate the performance of the Fast-J code for this case, simulated and measured \( \text{jNO}_2 \) values were compared by running the code along the DC8 flight track on the 18 July (see Fig. 2). This flight was chosen because a clear signal was seen in the
measured data when the aircraft passed through the BB aerosol layer (as seen by the on-board aerosol lidar), and measured photolysis rates were reduced. In a run with no clouds or BB aerosols the model significantly overestimates the data between 18h15 and 21h30. This time window corresponds to an increase in the measured upward jNO₂ flux and high aerosol scattering ratios observed by DC8 backscatter lidar at low levels indicating the presence of low cloud. The agreement is partially improved by including a low cloud layer (see Fig. 2, blue rectangle) with an OD of 5 extending from 0 to 0.5 km between 18h15 to 21h30 (continuous line). However, measured jNO₂ is still overestimated in the BB plume (see coincident CO data). A further run was performed including a BB aerosol layer with an OD of 0.3 (see Fig. 2, red rectangle) co-located with the high aerosol scattering ratio signal measured by the DC8 lidar between 4 and 11 km (Fig. 3). AOPs were prescribed as discussed in the previous sections. The 30% reduction in jNO₂ observed in the BB plume (dashed line) is now simulated well by the model suggesting that the AOPs used in the Fast-J code are reasonably realistic. Observed photolysis rates of other species like O₃ or PAN are also reduced in the BB plume, and well simulated by the run including the effects of BB aerosols. The impact of these changes on O₃ levels are discussed in the next section.

5. Results

In this section, results are discussed from CiTTyCAT simulations initialized with data on 18 July and run for 5 days. Firstly, the impact of high aerosol loading on photolysis rates, and photochemistry in the plume are discussed. Then, the influence of both chemical processes, and dynamical processes related to mixing with other air masses during
transport, are examined, and results compared to observations collected downwind during the Lagrangian matches.

5.1. Aerosol impact on photolysis rates

Concerning the inclusion of BB aerosols in Fast-J for this case, several assumptions, and simplifications had to be made. The aerosol layer was assumed uniform in aerosol concentration, and its thickness was varied from 7 km on the 18 July to 3 km on 23 July with the OD decreasing linearly from 0.3 to 0.13 over 5 days. It was also assumed that the trajectory was situated in the middle of the BB plume. The DC8 lidar data (see Fig. 3) confirms that the DC8 match is, indeed, in the middle of the BB plume, and the CO vertical profile measured by the Falcon on the 23 also shows that the Falcon match is approximately located in the middle of the plume.

In this study, BB aerosols were considered as an internal mixture of black carbon, an absorbent component, and sulfate, which has scattering properties. In an absorbing aerosol layer, available light is reduced, and therefore photolysis rates decrease whereas they can be enhanced in a scattering aerosol layer. For a mixture, the relative influence of scattering versus absorption depends on the solar zenith angle, SZA. Scattering properties outweigh absorption properties at low SZA, but their influence decreases with SZA. This dependence of the scattering/absorption with SZA is dominated by the shape of the aerosol phase function which can vary strongly depending on the refractive index, and the size distribution of the aerosols. SZA dependence was strong for the BB aerosols in this case, and at lower SZA the photolysis rates were even enhanced when aerosols were included. Consequently, measured photolysis rates should be analyzed carefully because changes due to the presence of BB aerosols will depend on SZA, and therefore on the
time of the day when the measurements were made. Another important aspect of the BB AOPs is their dependence on the size parameter $2\pi r/\lambda$. For small particles, this leads to an inverse dependence of the single scattering albedo on wavelength in the UV. This means that for a single particle, smaller wavelengths will be absorbed less. However, a plume contains thousands of particles which interact with each other leading to more complex effects which depend, not only on the single scattering albedo, but also on SZA, the optical depth, and the aerosol phase function [Reuder and Schwander, 1999].

The BB aerosol impact obtained by averaging over the 5 day simulation was found to be a reduction in all photolysis rates, and in particular, a reduction of -21% for $j\text{NO}_2$ compared to -22% for $j\text{O}_3$. This can be compared with results from Duncan et al. [2003] for Indonesian fires where monthly averaged reductions in $j\text{NO}_2$ and $j\text{O}_3$ in the FT over source regions were around -10 to -20% using a mean AOD of 0.3. Simulated photolysis rate reductions in a Mexican fire transported into Arizona were larger (-20 to -60%), but this study used a lower value of the single scattering albedo (0.82) than used here [Kotamarthi et al., 2006]. Also, in contrast to our simulation, $j\text{NO}_2$ was reduced more than $j\text{O}_3$ because different size distribution and refractive index were used. This shows that results are very sensitive to the AOPs parameters used for particular fire events.

In this case, the reduction in photolysis rates leads to a slowing down of the photochemistry with a reduction of -18% in $O_3$ production and -24% in $O_3$ destruction. $O_3$ production is reduced mainly because lower $j\text{NO}_2$ leads to reductions in NO plus $\text{HO}_2$. $O_3$ destruction is mainly due to the reaction of $O^1D$ with water vapor, and this term is reduced the most when aerosols are included due to the reduction in $j\text{O}_3$. But, this term, and also the second most important $O_3$ loss term (reaction of $O_3$ with $\text{HO}_2$) are also...
reduced due to lower O$_3$ levels resulting from less O$_3$ production. The overall effect of including these effects on net O$_3$ production depends on the balance between production and destruction. Changes in photolysis rates due to the inclusion of BB aerosols will reduce net O$_3$ production in a plume mainly producing O$_3$, and increase net O$_3$ production in a plume mainly destroying O$_3$. It will be seen in section 7 that after 8 days of simulation, the plume enters a net O$_3$ destruction regime. From this moment, the reduction in photolysis rates leads to an increase in O$_3$ production.

### 5.2. Chemistry only simulation including aerosol radiative effects

Simulated concentrations over 5 days of CO, O$_3$, NO$_y$, NO, PAN and water vapor are shown in Fig. 4, and compared to the range of measured values along the matching Lagrangian segments on the 20 July (BAe146), and the 23 July (DLR Falcon). In order to better characterize the variation of the chemical composition in the plume, 3 chemical initializations were used. One using mean observed DC8 values (black lines), and two others using mean ± standard deviation (std) values (red and blue dashed lines). It should be noticed that the red (blue) simulation corresponds to initialisation with the mean +std (-std) for species like CO, VOC, PAN but the mean -std (+std) for O$_3$, since O$_3$ is anticorrelated with precursors such as CO.

The first important discrepancy in the results is found in the simulated and observed concentrations of CO. The small CO decrease observed during the first 2 days is well reproduced by the model but after 5 days CO is overestimated by more than 150 ppbv. NO$_y$ is also overestimated by about 1000 pptv after 5 days. As will be seen in the next section, these overestimations are likely to be due to dilution of the plume during transport.
Despite the large discrepancies in CO and NO	extsubscript{y}, it is still interesting to examine this chemistry-only simulation in order to understand the photochemical processes in such BB plumes during long-range transport. The large O\textsubscript{3} increase, of about 17 ppbv observed over 5 days between the DC8 and the Falcon matches, is reproduced, and even overestimated by the chemistry-only simulation giving a mean O\textsubscript{3} increase of 22 ppbv in 5 days just due to photochemistry.

Diagnosis of model results for these chemistry-only simulations shows that the large increase in O\textsubscript{3} is mainly due to the high PAN loading in the plume. PAN is stable at low temperatures encountered during the first 2 days of the simulation, but rapidly decomposes at high temperatures encountered once the plume subsided leading to release of NO\textsubscript{2}, and resulting in increased O\textsubscript{3} production. Unfortunately downwind PAN measurements are not available but modeled NO values fall within the range of the observations on both on the 20 and 23 July. Note that in these runs, NO\textsubscript{y} levels in the plume are maintained because part of the NO\textsubscript{2} released from PAN decomposition is transformed into HNO\textsubscript{3} which makes up about 30% of the NO\textsubscript{y} level on 23 July.

In order to illustrate the effect of temperature on PAN decomposition, several stationary steady state runs at a fixed position corresponding to the location where the DC8 sampled the plume, were performed. Mean DC8 measurements, together with scaled PAN, in the plume were used for the chemical initialization, and only the temperature varied between each run. Values of PAN and O\textsubscript{3} after 1 day of simulation are shown on Fig. 5. At temperatures lower than 260 K no changes in PAN are seen. PAN thermal decomposition begins at temperatures higher than 260 K, and is non-linear with temperature especially beyond 270K. At 290K, 90% of the initial PAN is decomposed after 1 day. Therefore,
increasing temperature higher than 290 K will not have a strong effect as most of the PAN has already been decomposed thus limiting the potential for further O\textsubscript{3} production. It is interesting to note that the value of 90\% PAN decomposition after 1 day at 290K is not dependent on the initial PAN value. This also explains why, in the simulation, even if the simulated temperature increases by 25 K (from 240 to 265 K) between the DC8 and the BAe146 matches, only a small fraction of PAN is decomposed.

In model runs with and without PAN, it was found that PAN decomposition accounts for 80\% of the total O\textsubscript{3} increase between DC8 and Falcon matches. In the run without PAN, conversion of the initial NO loading into O\textsubscript{3} through NO\textsubscript{2} photolysis is only sufficient to maintain net O\textsubscript{3} production during the first 2 days resulting in net O\textsubscript{3} destruction over 5 days. Since PAN has a central role in governing O\textsubscript{3} production, it is important to consider uncertainties in the PAN decomposition rate which can vary by ±100\% at 280K according to the latest IUPAC recommendations (http://www.iupac-kinetic.ch.cam.ac.uk). Increasing this rate by a factor of 2 leads to faster PAN decomposition, lower PAN (by 500 pptv), and higher O\textsubscript{3} (by 6 ppbv) concentrations on 23 July. However, this represents a 10 ppbv overestimation of the Falcon data.

It is clear that physical variables such as temperature and water vapor are also important in governing the production, and destruction of O\textsubscript{3} during long-range transport of such plumes. Comparison of observed values in the plume, and values interpolated from ECMWF analyzes are shown in Fig. 4. Analyzed and measured water vapor, as given by specific humidity agree well. Nevertheless, it is interesting to see how O\textsubscript{3} levels respond to changes in water vapor. Water vapor in the plume is low during the 5 first days so that halving the water vapor content in the model has a very small impact on
$O_3$ net production (less than 1 ppbv). On the contrary doubling the water vapor content along the trajectory increases $O_3$ destruction, and leads to a decrease of 18% in net $O_3$ production.

Measured and simulated temperatures agree reasonably well except at the beginning of the simulation where temperatures are underestimated by more than 7K on the 18 July, in part because the trajectory used passes slightly above the DC8 match. However, increasing the initial temperature to match the measured one does not change $O_3$ production as both temperatures are too low for PAN decomposition. Measured temperatures during the BAe-146 and the Falcon matches are similar but ECMWF analysis show that between these two matches, the temperature reached 278K (at the southern most point along trajectory), which leads to the large $O_3$ production. A sensitivity test with a constant temperature between these two matches gives a decrease of 41% in net $O_3$ production, and therefore much lower $O_3$ after 5 days (9 ppbv less).

These sensitivity studies show how important specific humidity and temperature are for $O_3$ chemistry. Therefore, it is important that meteorological parameters used by models agree as closely as possible with observations. The evolution of meteorological parameters along the plume transport pathways is also crucial for estimating $O_3$ levels, so that photochemical evolution cannot be inferred from measured values alone. It will also be shown (in section 7) that water vapor and temperature play a key role in determining $O_3$ levels in plumes transported into the lower troposphere where high water vapor can lead to strong $O_3$ destruction balanced by $O_3$ production through PAN decomposition.

Overall, whilst chemical changes alone could explain observed $O_3$ changes during plume transport, they cannot explain the observed changes in CO and NO$_y$. 
5.3. Simulation of mixing/dilution of the BB plume

In the previous section, model runs with no mixing were discussed, and the plume was assumed to be isolated from the background and not diluted. In the real atmosphere, a plume is subject to stirring by large-scale winds followed by mixing. This mixing process entrains surrounding air masses, and thus changes concentrations in the plume [Stohl, 2001]. The scheme for mixing in CiTTyCAT is a simple linear relaxation scheme [Evans et al., 2000] resulting in an exponential decay of plume concentrations towards background concentrations. The rate of mixing is defined by the e-folding timescale $K_{mix}$ in day$^{-1}$ which can also be written in terms of a mixing timescale $\tau$ in day ($\tau = \frac{1}{K_{mix}}$).

This scheme requires the estimation of so-called background concentrations as well as the mixing timescale. In this study, instead of trying to estimate average background concentrations, concentrations were defined using in-situ measurements in air masses adjacent to the BB plume. The mixing timescale was chosen in order to obtain the best agreement between measured and modeled CO which is a good tracer for mixing since it is relatively long-lived on the timescales considered here, and not strongly affected by chemistry. A strong decrease in CO is thus characteristic of mixing/dilution of the plume.

Analysis of observed CO in the plume showed a small CO decrease between the DC8 and the BAe146 matches, and a much stronger one between the BAe146 and the Falcon, when the plume reached western Europe (decrease of 40% of BAe146 CO). Trajectory analysis showed that just south of the BAe-146 match, trajectories reached a stagnation point and switched from descent in quiescent clear air to being near a warm conveyor belt moving up from the southwest that was likely to be more turbulent. This resulted in a change in direction in the transport pathway (see Fig. 1). It is thus realistic to simulate...
two mixing regimes representative of these different situations: a slow mixing timescale (20 days) during the two first days of simulation following by a faster one (5 days), leading to an integrated mixing timescale of 6.25 days.

The values of these mixing timescales, chosen to match the CO measurements, are dependent on whether the same parts of the plume were sampled since, in reality, strong gradients exist at plume extremities. Lagrangian matches are not perfect and it is possible, for example, that the Falcon may have missed the center of the plume sampled by the DC8 explaining the large difference in measured CO. However, other parts of the same large plume were sampled over Europe by different platforms and the measured CO was in the same range as the Falcon data or lower (see section 7). It is also worth noting that, if the same mixing rates are applied to aerosols in the plume (i.e. mixing the DC8 OD with a zero background), this leads to a decrease from 0.3 to 0.128 after 5 days, which is consistent with the estimated OD on the 23 July from in situ measurements and lidar data. This supports the choice of the mixing rates used in this study.

Concerning background values, Methven et al. [2006] showed that this BB plume was situated within a dry intrusion that had descended from close to the tropopause over North America. DC8 measurements of CO, O$_3$ and data from the O$_3$ and backscatter lidars also clearly show that the BB plume was in close proximity to air with low CO and high O$_3$ concentrations, characteristic of the UT. It is therefore reasonable to imagine that the BB plume and UT air masses have mixed. Therefore, initially, the DC8 measurements in the UT air mass were used to constrain background concentrations (see Table 4) together with a mixing timescale of 20 days during the first 2 days and 5 days during the last 3
days. In results from this run (not shown) O_3 was overestimated by more than 7 ppbv compared to the Falcon measurements.

Examination of ECMWF water vapor suggests that there was the mixing of wetter air into the plume where the trajectories change direction (see water vapor on Fig 4). This corresponds to when the BB plume lost contact with drier air above and to north, and came into contact with more moist air from the south associated with a warm conveyor belt. Evidence for this split between the BB plume and UT air masses is also seen in satellite water vapor images for the 20 and 21 July (Cooper, pers. comm., see http://www.al.noaa.gov/csd/metproducts/icartt2004/). Therefore, a second run was performed where both the mixing time scale and background concentrations were changed after 2 days in an attempt to represent changes in the composition of air masses mixing into the BB plume. In fact, air masses sampled by the Falcon next to the plume on the 23 July were typical of free tropospheric (FT) air masses, and had higher water vapor content and lower O_3 than the UT air mass. These measurements were used to constrain background concentrations during the last 3 days of the simulation (see Table 4).

Results using UT/FT background concentrations are shown in Fig. 6. Simulated O_3 and CO agree very well with Falcon measurements giving some confidence in the hypothesis that the BB plume mixed first with a UT air mass before mixing with a FT air mass. As both UT and FT mixed air are poor in PAN and HNO_3, NO_y in the plume is reduced by about 1000 pptv leading to very good agreement with the Falcon measurements. The final breakdown in modeled NO_y is 55% PAN, 3% NO_x and 42% HNO_3. Simulated NO values are still in the range of measurements because NO level are governed by photochemistry in the plume (PAN decomposition), and are not strongly influenced by mixing.
It is interesting to note that mixing not only changes concentrations in the plume by introducing background air, but can also change the photochemistry in the plume. In this case, the main effect is dilution of PAN in the plume leading to a reduction of net \( \text{O}_3 \) production in the plume by 10%.

Overall, these results show that inclusion of mixing processes, albeit in a simple manner, produce results in better agreement with the full range of measurements.

6. \( \text{O}_3/\text{CO} \) correlations

In the previous section, it was shown that a combination of photochemistry and mixing with UT/FT air masses can explain the evolution of the BB plume since the results agree reasonably well with the observations for several trace gases. However, it is very difficult to know the real composition of mixed air masses, and thus to evaluate the relative contributions of photochemistry and mixing. For example, mixing of the plume with a UT air mass could lead to a large \( \text{O}_3 \) increase in the plume even if the plume does not undergo any photochemical production. It is therefore possible that both photochemistry and mixing simulations could be incorrect but that the final results could match the observations because the effects of the different processes compensate each other. However, the proposed scenario can be tested in more rigorously by looking at the evolution of trace gas correlations, and more specifically the slope of such correlations. Here, we focus on the \( \text{O}_3/\text{CO} \) correlation since \( \text{O}_3 \) can change rapidly over several days due to photochemical processes, and CO is a good tracer of mixing over this time period. Indeed, if mixing in the plume is uniform, then \( \text{O}_3/\text{CO} \) correlations are not changed by mixing processes and, in the absence of loss processes, any change in the slope can be attributed to photochemical processes alone. This assumes that all parts of the plume are mixed with the same
background, and with the same mixing timescale at any point in time as was assumed here in Section 5.3. Considering that the plume evolution is followed during only 5 days, and that the segment matches correspond to inside the plume and not the edges, this hypothesis of uniform mixing seems reasonable. Mixing processes could also have indirect effect on O$_3$/CO slopes ($\delta$O$_3$/\delta CO) by diluting O$_3$ precursors, and so modify photochemical processes in the plume.

The case studied here is particularly interesting to look at in terms of O$_3$/CO correlations since a 4 day old BB plume was measured by the DC8 with a negative $\delta$O$_3$/\delta CO value, an unusual feature in an ageing BB plume (see Fig. 7). Negative values of $\delta$O$_3$/\delta CO have been measured in young BB plumes due to titration [Stith et al., 1981; Hobbs et al., 2003] but most BB plumes observed during previous campaigns showed rapid O$_3$ production, and positive $\delta$O$_3$/\delta CO values after just 1 or 2 hours [Goode et al., 2000; Andreae et al., 1988]. $\delta$O$_3$/\delta CO measured by the BAe146 in the BB plume was still negative, but with a less steep slope than the DC8 (i.e. 6 days after emission). Aged BB plumes with negative correlations have also been observed at the PICO-NARE station on the Azores during the ICARTT campaign ValMartin et al. [2006]. The reason for these negative correlations in aged BB plumes is not clear. It does not necessarily mean that the plume has not undergone any photochemical O$_3$ production but that the O$_3$ production was not strong enough to change the initial negative slope to positive. High aerosol loadings over the source regions [Stohl et al., 2006; Duck et al., 2006] might have strongly dampened initial O$_3$ production in these plumes or else other processes such as O$_3$ loss by reaction with organic component present in aerosols or nighttime chemistry including the of heterogeneous hydrolysis of N$_2$O$_5$ [ValMartin et al., 2006] might have played a role.
In contrast, the $\delta{O_3}/\delta{CO}$ measured by the Falcon was positive (see Table 5) with a value of 0.078. This change from negative to positive slope after 5 days indicates that the plume is strongly chemically active as already suggested by the model results discussed previously. The slope value measured by the Falcon is in the lower range of values reported for previous campaigns which range enormously from 0.045 to 0.88 [Andreae et al., 1988, 1994; Goode et al., 2000]. It is also lower than values reported by ValMartin et al. [2006] for BB plumes with positive correlations observed during the ICARTT campaign at the PICO-NARE station ranging from 0.14 to 0.89. However, direct comparison of $\delta{O_3}/\delta{CO}$ is difficult because, in our study, the slope calculation is made in the Lagrangian sampling of the plume which does not include, for example, the edges of the plume, and represents only CO values larger than 150 ppbv (for the Falcon match). Using PICO-NARE measurements, Pfister et al. [2006] showed that if CO thresholds used to calculate $\delta{O_3}/\delta{CO}$ slopes in a plume are increased from 100 to 120 ppbv, then the slope value is almost divided by a factor 2 (from 0.44 to 0.26). This shows that $\delta{O_3}/\delta{CO}$ values are very sensitive to the range of values selected in the calculation.

Therefore, in order to test the scenario put forward in the previous section, and in particular, the photochemistry in the model, multiple model simulations were conducted, initialized with DC8 measurements averaged every 30s during the match segment. Modeled and measured $O_3$/CO correlations and slopes were then compared downwind. With this method, each run represents a different part of the plume (black crosses in Fig. 8) observed by the DC8, and thus the gradient across the plume. Simulation and comparison of $\delta{O_3}/\delta{CO}$ are relatively common with global models but, to our knowledge, this is the first time that such simulations have been performed with a photochemical trajectory...
model. Results from the multiple simulations after 2 (red triangles) and 5 (blue diamonds) are shown for chemistry only runs (Fig. 8a), and chemistry plus mixing (UT/FT) runs (Fig. 8b). Observed $O_3$/CO correlations are represented by linear fits to the data (continuous lines). Measured and simulated slopes on the 20 and 23 July are also summarized in Table 5. Overall, the model simulations reproduce very well the change of $\delta O_3/\delta CO$ from negative for the DC8 and the BAe146 samplings to positive for the Falcon match. Values of the $O_3$/CO slope are relatively well simulated but slightly underestimated. The results show that the main effect of mixing is to translate simulated $O_3$/CO correlation lines towards background CO and $O_3$ levels leading to better agreement with the range of measured concentrations. Only small changes are found between $O_3$/CO slopes for simulations with (slope of 5.1%) and without (slope of 5.2%) mixing. The slope is slightly decreased in the mixing run due to dilution of $O_3$ precursors which decreases $O_3$ production. In the following discussion all calculated slopes are from chemistry plus mixing simulations.

There are two explanations for the small discrepancy between measured and simulated $\delta O_3/\delta CO$: the 3 matches are not perfect, and the limits of the matching plume are slightly different, or the model slightly underestimates the production of $O_3$ per quantity of CO, even if it reproduces the main features of the photochemical evolution of the plume. Concerning the possibility that different parts of the plume were sampled, it can be seen in Fig. 8b that the measured CO values during the Falcon match are more dispersed than those simulated by the model. This can signify that the limits of the Falcon match are too large. For example, reducing the Falcon match window by 2 minutes leads to a reduction in the measured slope from 7.8% to 6.1%, which is closer to the simulated value.
Concerning the hypothesis of an underestimation in the modeled $O_3$ production, two hypotheses have been examined: an increase in photolysis rates due to the presence of clouds, and an increase in the PAN decomposition rate (see Section 5.2). Satellite images show that low clouds were present over Europe from 22 to 23 July, and Falcon jNO$_2$ data collected on these two days often showed a strong variability with some very high values, typical of broken cloud fields. To see if an increase in the J-values due to the presence of low clouds could increase $\delta O_3/\delta CO$, sensitivity tests using different cloud ODs on 22 and 23 July were performed. $\delta O_3/\delta CO$ after 5 days of simulation were compared (see Table 5 for details). $\delta O_3/\delta CO$ increases slightly when increasing cloud OD, up to 6.3% with a cloud OD of 20. An increase by a factor two in the PAN decomposition rate leads to a final slope of 6.5%. In both cases, simulated $\delta O_3/\delta CO$ are closer to the measured one but mean simulated $O_3$ levels in the plume are now overestimated by about 3 to 6 ppbv. Only a change in the mixing scenario could lead to better agreement with the mean plume value but this would require mixing with air masses with much lower $O_3$ and no evidence for such air masses was found in the measurements made near the plume. In the case of doubling the PAN decomposition rate, NO$_y$ values in the plume are also slightly underestimated. It is finally difficult to conclude on the reason for the small difference between simulated and observed slopes. It is likely due to combining effect of non perfect match window and small underestimation of photochemistry due to either increased in photolysis rates over clouds (which are not simulated) or underestimation in the PAN thermal decomposition rate.

Overall, examination of changes in $O_3/CO$ slopes has allowed more rigorous validation of the contribution of photochemistry to $O_3$ changes in this BB plume since the model is able
to reproduce the change from negative to positive slope. These results give confidence in the modeled photochemical contribution, and support the results presented in Section 5.3. They confirm that significant O₃ production took place during the plume transport, and that mixing had a large influence on CO concentrations.

7. Possible influence on O₃ levels in the European lower troposphere

The Lagrangian analyses presented in the previous sections have shown that, for the particular case under investigation there was a strong enhancement in O₃ due to photochemistry after 5 days. Other studies have examined the influence of boreal forest fires during this period on the O₃ budget over the North Atlantic. For example, Pfister et al. [2006] estimated a 10% contribution to the tropospheric burden at the end of July 2004. Cooke et al. [2006] also estimated an O₃ increase of 6 ppbv in the boundary layer over the United Kingdom from 21 to 23 July 2004 due to BB emissions, but did not find any measurements to support their findings. However, global models often underestimate concentrations of pollutants in plumes due lack of horizontal and vertical resolution [Bousserez et al., 2006; Pfister et al., 2006], and may therefore underestimate the impact of BB events downwind over Europe. In this section, we extend the previous analysis further downwind in order to investigate the possible influence of the case examined here on O₃ in the lower troposphere, and the boundary layer over Europe. In the future, it would be interesting to examine other cases, and to compare these results with global models.

For the period 23 to 26 July we have examined data collected at surface sites to see whether there is evidence of transport of the BB plume studied here into the lower troposphere or boundary layer over Europe. FLEXPART simulations, run with CO BB
tracers, showed that a large part of the plume was transported northwards over Scandinavia with a significant fraction transported also over central Europe, and finer scale filaments transported southwards over France and the Mediterranean. Data was examined from Observatoire de Haute Provence (OHP) (43°55N, 5°42E) in southern France where two O$_3$ lidars and a backscatter lidar were operated during the ITOP campaign (see Ravetta et al. [2006] for details); Jungfraujoch (lat:46°55N, 7°98E) at 3.6 km altitude in the Swiss Alps where measurements of many trace constituents including CO, O$_3$ and several hydrocarbons were made as well as meteorological variables, and aircraft profiles of CO and O$_3$ from the Measurement of OZone, water vapor, carbon monoxide and nitrogen oxides by In-service Airbus airCraft (MOZAIC) programme [Nedelec et al., 2005].

Analysis using back trajectories identified the following features which appear to be linked to the Lagrangian case discussed in the previous sections (see Fig. 9). Even if the different samplings are not directly linked in the Lagrangian sense, they were probably initially part of the same large plume.

A MOZAIC flight over Paris on the 23 July confirmed the presence of the layer seen by the DLR Falcon on the same day. Ozone lidar data collected at OHP on the 24 July showed a layer at 3 to 4km which was linked to the larger plume, if not exactly the same part of the plume sampled earlier by the Falcon. Measurements made during the period 24 July to 26 July at Jungfraujoch are shown in Figure 10 together with results from the FLEXPART BB tracer simulations when observed CO concentrations exceeded 200 ppbv. Trajectories analysis show that on the 24 July these enhancements were linked to a part of the larger plume when it was transported into the lower troposphere over Europe. Trajectories also
suggest that this air mass continued to descend into the European boundary layer over eastern Europe and Mediterranean.

In order to evaluate the possible contribution of this BB plume on \( O_3 \) levels over Europe the runs discussed in section 5 were run for a further 5 days from 24 to 28 July, and compared to the data from OHP, Jungfraujoch and MOZAIC (Paris). The results are shown in Figure 11 over 10 days. For the last 5 days of simulation, the aerosol OD was fixed at 0.13 and a mixing rate of 5 days. FT background concentrations were used to constrain background concentrations as the plume was mainly transported in the FT, and no measurements were made in the proximity of the plume after the Falcon match. Simulated CO agrees reasonably well with the observations at Jungfraujoch when mixing is taken into account (pink shaded area) even if \( O_3 \) concentrations at Jungfraujoch are slightly overestimated. It is also interesting to note that the modeled \( O_3/CO \) slope continues to increase up to 11% until the plume enters a destruction regime when slope starts to decrease. Observed and modeled \( O_3/CO \) slopes at Jungfraujoch on the 24 July are very similar, 7.5\% and 7.7\%, respectively. Agreement with observed \( O_3 \) at OHP, where \( O_3 \) levels were higher (around 80 ppbv), is less good supporting the idea that a different part of the plume was observed over southern France. The proximity of a tropospheric fold above the layer (also seen by the OHP lidar) suggests that additional mixing may have taken place with air masses of upper tropospheric origin.

Bearing in mind the caveats that this is not a truly Lagrangian analysis, and that mixing and aerosols conditions were less well constrained for the last 5 days of the plume evolution, it is still possible to use the results to examine the relative contributions of photochemistry and mixing to \( O_3 \) levels in the plume after 10 days of transport. As
noted above, results from the run including mixing give better agreement with the data further downwind, especially over Jungfraujoch, and suggest that the net change in O$_3$ after 10 days was very small or even negative. However, mixing processes mask the impact of photochemistry considerably by diluting the signature of the BB plume over Europe. Results from a chemistry-only simulation (blue shaded area) show that the plume was in a net O$_3$ production regime during the first 8 days of simulation leading to an increase of 30 to 40 ppbv over this period, primarily as a result of PAN decomposition. During the last 2 days there is net O$_3$ destruction over Europe when PAN is almost completely decomposed due to elevated temperatures and water vapor has increased strongly. The net change in O$_3$ for the chemistry only simulation over the 10 day period is 8 to 12 ppbv.

Despite the dilution effect on pollutant levels in the plume, it is clear that BB plumes can have an impact on CO and O$_3$ levels in the European lower troposphere and even the boundary layer since the data and model simulations show high levels of both species over Europe between the 22 and 26 July. Several other BB plumes were also sampled over Europe during the ITOP campaign. For example, the Falcon sampled BB plumes several times with enhanced CO (up to 350 ppbv), O$_3$ (up to 100 ppbv) and NO$_y$ (up to 2500 pptv) including one low level case on 26 July off the coast of France at 1.5 km when CO was 270 ppbv and O$_3$ was 95 ppbv. MOZAIC profiles collected during the campaign period also showed many plumes with enhanced CO (up to 300 ppbv) and O$_3$ (up to 85 ppbv) over Paris, Frankfurt and Vienna between 3 and 7 km which are likely to be BB plumes with such high CO concentrations. All these plumes give different O$_3$/CO slopes ranging from 4% to 40%. This likely reflects their different histories in terms of temperature and humidity which, as shown previously, can have a large impact on net photochemical O$_3$
production. This is particularly true for such BB plumes which have high PAN loadings. These results show that it is necessary to be very careful when attributing O$_3$ changes to photochemistry alone since mixing with other air masses can also have a significant impact. It may also makes detection of O$_3$ anomalies linked to long-range transport of pollutants into the European lower troposphere or even the boundary layer extremely difficult.

8. Conclusions

A case of a BB plume transported from Alaska to Europe, has been analyzed using a Lagrangian approach. This plume was sampled three times by different aircraft during the IGAC Lagrangian 2K4 campaign (summer 2004) over the northeast North America, the North Atlantic and Europe. Lagrangian match segments along the flight tracks were defined by Methven et al. [2006] using a combined trajectory/VOC fingerprint analysis. Measurements in the plume show an O$_3$ increase of 17 ppbv over 5 days together with a significant decrease in CO, and a change from negative to positive O$_3$/CO correlations over the same time period.

The CiTTyCAT model has been used to study the processes governing the chemical evolution of the plume, and in particular, changes in O$_3$. The model was initialized with upwind measurements in the BB plume, and compared with downwind measurements. The influence of high aerosol loadings in the plume on photolysis rates during long-range transport was taken into account by combining in-situ aerosol measurements in the BB plume and lidar measurements with a photolysis module (Fast-J), implemented in CiTTyCAT. The impact of BB aerosol on photolysis rates was -21% for jNO$_2$ and -22% for jO$_3$ with the overall impact leading to a reduction of photochemistry in the plume: O$_3$ pr-
duction was reduced by 18% and \(O_3\) destruction by 24% leading to less net \(O_3\) production overall. Factors such as single scattering albedo, optical depth and phase function were found to be important. These results show that such BB aerosol effects on photochemistry can be important and should be taken into account in chemical model simulations.

Despite the slowing down of photochemistry in the plume due to the aerosols, the model predicts that the plume was very chemically active. Net \(O_3\) production was estimated to be 22 ppbv over 5 days with a chemistry-only run. This large \(O_3\) production in the plume was driven by thermal decomposition of PAN which was very elevated in the plume, and made up 80% of \(NO_y\) during the upwind sampling by the DC8. Temperatures, which were low initially, warmed by more than 30K along the plume pathway leading to this PAN decomposition. Low water vapor content (measured) in the plume also helped to maintain this high net \(O_3\) production.

It was also shown that the chemistry-only simulation was not able to reproduce observed values of certain pollutants, especially CO and \(NO_y\) after 5 days, and that mixing/dilution of the plume must also have been important. In-situ measurements collected in close proximity to the plume were used to constrain background concentrations, and mixing timescales were chosen to obtain the best agreement between modeled and observed CO in the plume in relation to the meteorological situation of the flow. The best results were obtained by using concentrations representative of a UT air mass during the first 2 days, and FT concentrations during the last 3 days with mixing timescales of 20 days and 5 days, respectively (giving an integrated mixing timescale of 6.25 days). With this mixing scenario, simulated CO, O3, \(NO_y\) and NO levels were in the range of observations made in the plume after 2 and 5 days.
Results using multiple model simulations were also used to test more rigorously the contribution of photochemistry to observed changes by comparing simulated and observed O₃/CO slopes in the plume. The change from negative to positive correlation during transport across the North Atlantic was well simulated by the model even if the observed slopes were slightly underestimated. These results confirm that the large increase in O₃ was due to photochemistry. Extension of the model runs for a further 5 days over Europe showed that once the plume entered the lower troposphere, O₃ destruction dominated. Dilution effects were also increasingly important, leading to only very small simulated O₃ changes after 10 days. These results are supported by comparison with available ground-based and aircraft data which showed evidence for this plume being transported into the lower troposphere over Europe.

Overall, the influence of Alaskan BB plumes on O₃ levels over Europe may have been particularly important at least in the FT as shown by the different BB plume samplings from aircrafts and ground based stations and as suggested by global model simulations [Pfister et al., 2006; Cooke et al., 2006]. However, O₃ changes in such plumes can vary a lot since they depend on its photochemical and physical history which will depend a lot on PAN loading, temperature and water vapor evolution along its pathway as well as dilution effects. The results presented here show that it is important to distinguish between these different processes.

Recent studies predict that boreal wildfires may increase in the future due to climate change [Stocks, 1998], and possibly increased direct human impact [Mollicone et al., 2006]. As forest fire plumes are likely to have high PAN loading due to the abundance of oxygenated volatile organic compounds (o-VOC) [Singh et al., 1994; Fan et al., 1994], their
ability to transport O$_3$ on intercontinental scales is large, and their impact is likely to be important over the entire Northern Hemisphere.

Acknowledgments.

Elsa Real and Kathy Law acknowledge financial support from national programmes (PNCA, PATOM) provided by INSU, ADEME and also from Insitut Pierre Simon Laplace (IPSL) as well as the Institut Geographique National (IGN) for hosting the DLR Falcon campaign at Creil, France. We would like to thank M. Haeffelin, C. Pietras and Y. Morille for making measurements using the IPSL-SIRTA aerosol lidar during the ITOP campaign and for subsequent analysis of the data. We also would like to thank the whole ICARTT team, and in particular, UK BAe-146 scientists (Lisa Whalley and Jim Hopkins for PAN and VOC data) and NASA DC8 scientists (Bill Brune (NO data), Ron Cohen (NO$_2$ data) Jack Dibb (HNO$_3$ data), Glen Diskin (water vapor), Vince Brackett and John Hair for aerosol data and aerosol optical depth retrievals). We also express our gratitude to NABEL-BUWAL in Switzerland for access to the chemical data from the Jungfraujoch site, and Philippe Nedelec for provision of MOZAIC O$_3$ and CO data.

Figure 1. Flight tracks of the DC8 (18 July), the BAe146 (20 July) and the Falcon (23 July) (black dashed lines). Lagrangian matches along the flights are represented in red together with FLEXTRA backward trajectories from these matches (blue for the Falcon, pink for the BAe-146 and violet for the DC8).
Figure 2. DC8 measured CO (black line) and jNO$_2$ (blue dashed line) together with simulated jNO$_2$ along the flight with (pink dashed line) and without (pink solid line) aerosols. A low cloud layer was simulated at the blue rectangle location, and the BB plume at the red rectangle location. The largest jNO$_2$ variations are due to change in altitude of the aircraft (see flight track shown in Fig. 3).

Figure 3. Aerosol scattering ratio as measured by the DC8 on-board lidar on the 18 July 2004. A strong signal is seen at the same location as high CO in-situ data (18h30, 19h15) including the Lagrangian match (18h39 - 19h02)
Figure 4. CiTTyCAT simulations initialized with mean and standard deviation measurements in the DC8 plume are represented respectively as continuous black lines and dotted color lines (blue for mean - std, pink for mean + std), respectively. Vertical red lines correspond to measurements made in the plume by the BAe-146 aircraft (20 July, 202 Julian days), and the DLR Falcon aircraft (23 July), 205 Julian days). For the water vapor and temperature panel, the continuous line represents the simulated water vapor and the dotted line the simulated temperature. Red and green vertical lines represent the water vapor and temperature measurements, respectively.

Figure 5. Change in PAN and \(O_3\) after 1 day of fixed simulation with different temperatures at the location and time of the DC8 plume sampling.
Figure 6. CiTTyCAT simulations including mixing with a mixing timescale of 20 days during the first 2 days and 5 days during the last 3 days. Same caption as Fig. 4. Background concentrations are given in Table 4.

Figure 7. Observed O₃ versus observed CO from the DC8 match (black crosses), the BAe146 match (red triangles) and the Falcon match (blue diamonds).
Figure 8. Measured O$_3$ versus CO from the DC8 match (black crosses) used as initialization for the CiTTyCAT model, simulated O$_3$ versus simulated CO after 2 days of simulation (red triangles) and after 5 days (blue diamonds). The lines represent fits to the measured correlations in the DC8, BAe-146 and Falcon matches, a) simulation without mixing, b) simulation with mixing, see text for details.

Figure 9. 10 day backward trajectories from Jungfraujoch on the 24 July (pink), OHP on the 24 July (red), the Falcon BB plume sampling (green), and the MOZAIC BB plume sampling (blue) on the 23 July. Crosses correspond to the initial trajectory release time, stars to the BAe-146 mean match time (20 July, 12h30) and diamonds to the DC8 mean match time (18 July, 19h).
Figure 10. Measured CO (black line) and O$_3$ (pink line) at Jungfraujoch during July.

Influence of BB plume are seen from the 24 July to the 26 July

Figure 11. Simulated O$_3$, CO, PAN, water vapor (continuous line) and temperature (dashed line) in the plume over 10 days with (pink) and without (blue) mixing. Measurements made by the BAe146 on the 20 July (red), the Falcon (red) and MOZAIC aircraft (green) on the 23 July, the OHP lidar (only O$_3$, orange) on the 24 July, and at Jungfraujoch on the 24 July (violet) are represented as vertical lines).
