Abstract—We present Single Event Effect (SEE) and Total Ionizing Dose (TID) data for 1 Gbit DDR SDRAMs (90 nm CMOS technology) as well as comparing this data with earlier technology nodes from the same manufacturer.

Index Terms—radiation effects, reliability estimation, statistics, quality assurance, probability.

I. INTRODUCTION

Synchronous Dynamic Random Access Memories (SDRAMs) are both a cutting edge CMOS technology and an enabling technology for space flight. As such, radiation test results are of interest to both technologists and designers. Single event latchup (SEL) response is a major concern, since it has made recent commercial memory generations difficult and expensive to qualify. This is because even for parts that remain functional after SEL, reliability may be compromised by latent damage.[1] Despite such challenges and others relating to obsolescence and supply, lot-to-lot variability, and qualification expense, the advantages conferred by DRAMs over other memory solutions usually dictate their use for mass storage applications. In this poster, we present data on the Single-Event Effects (SEE) and Total Ionizing Dose (TID) susceptibility of Samsung 1 Gbit Double Data Rate (DDR) SDRAMs (K4H1G0438).[2]

Devices Tested: Samsung K4H1G0438
256M x 4 configuration
66-pin Thin Shrink Small Outline Package (TSSOP)
Internal speeds up to 266 MHz
Vdd: 2.5 V

Die Revisions (Revs):
NASA GSFC: Rev A (90 nm CMOS)
The Aerospace Corporation: Rev M (100 nm CMOS)

Test Systems:

Manuscript received July 8, 2006. This work was supported in part the NASA James Webb Space Telescope (JWST) Program and the NEPP Electronic Radiation Characterization (ERC) Project.

J. L. Gorelick is with Boeing Space and Intelligent Systems (BSIS), Los Angeles, CA USA, (jerry.l.gorelick@boeing.com).

NASA GSFC’s Low-Cost Digital Tester (LCDT) and Aerospace’s test system have been described previously.[3, 4]

Test Facilities – Heavy Ion

NASA GSFC performed tests at:
- SEE Test Facility (SEETF) at Michigan State University (high Linear Energy Transfer—LET).[5]
- Texas A&M University Cyclotron Center (TAMU – The 40 MeV/amu tune was used to ensure penetration to the sensitive volume from the front-side for low LET ions.)

The Aerospace Corporation used the Lawrence Berkeley National Laboratory’s (LBNL) 88-inch Cyclotron.

Test Facilities - Proton

The Aerospace Corporation used LBNL as well as the Indiana University Cyclotron Facility (IUCF). Proton energies at LBNL were 20, 30 and 50 Mev, while those at IUCF were 98 and 200 MeV. All proton testing was done at normal incidence.

HEAVY-ION SEE TESTING

NASA GSFC

Initial SEE testing was carried out at the SEETF on packaged devices. Due to temporal and economical constraints, testing was conducted with a single ion incident at 0°, 45°, and 60° to the DUT normal to give 3 effective LETs.
Effective LET in the active volume was calculated based on the energy lost by the ion beam as it traversed the layers over the sensitive volume (e.g., plastic molding, lead frame, etc.) [6] (See figure 2, for example.) Lead frame and package composition and thickness were derived from information supplied by the vendor.

An attempt was made to repackage several of the TSSOP DUTs to allow easier characterization at TAMU. This repackage was unsuccessful (timing/signal drive issues) and the higher energy (40 MeV/amu) tune was used to characterize the DUT in the low LET range. To ensure that ion LET could be determined unambiguously, only data for normal incidence ions are reported here. LET for the tests at TAMU was estimated using the same method as was used for the SEETF.

The Aerospace Corporation

Heavy-ion testing at the LBNL facility used a 10 MeV/amu tune, so the the DUTs be thinned to a thickness of 3 mils (about 120 µm) and mounted face down so they could be irradiated from the backside. All ions were incident normal to the device.

Test Methods

Similar testing methods were used by both NASA GSFC and The Aerospace Corporation. The test flow was as follows:

- Write DUT with a fixed test pattern
- Read back test pattern and verify.
- Begin Irradiation and read DUTs repeatedly
- If a reading differs from the programmed pattern, tally a single-event upset (SEU). Aerospace corrected the error before continuing reading, while GSFC did not.
- If a large number of errors occur simultaneously, and errors continue after the beam was stopped, we stop the run and tally a single-event functional interrupt (SEFI). If errors do not continue with no beam, the large error is tallied as a burst, block or column error.
- A SEFI causing a significant power supply current jump and not recovering after stopping the beam and refreshing device mode registers was called an SEL.

Because of the complexity of SEE data for SDRAMs, the addresses, values and times of all errors were recorded for post processing to extract multi-bit upsets, different SEFI modes, stuck bits, etc. The Aerospace Corporation conducted all irradiations at room temperature. GSFC looked for SEL susceptibility at both ambient temperature and at 85 °C.

Internal DUT frequencies were 100 MHz.

The Aerospace Corporation performed proton tests at LBNL and IUCF with a primary emphasis on SEE (similar method to heavy ion testing). TID data was taken noting only functional performance and supply current variances. No additional parametric measurements were made during testing.

III. DATA ANALYSIS

In terms of error types and complexity, an SDRAM is more like a microcontroller with a large memory array than a simple memory array. Effects of SEFIs are particularly important for most space applications [4, 7].

The two organizations independently performed data analysis. Though similar methodologies were utilized, SEFI definition and data parsing may have been differed. Additionally, the fact that there were two die revisions tested may skew results. No attempt was made to coordinate the analyses.

GSFC SEE Data Analysis

During postprocessing, based on the time stamps, addresses and memory contents, data were classified into:

- Single-bit Upsets (SBUs)
- Multi-bit upsets (MBUs)
- Burst errors (temporary strings of errors – self-recovering)
- Burst errors (persistent – non-recovering) classified as SEFI
- Address errors (multiple errors in same row, block, or column)
- SEL

Because statistics for the burst error modes and address errors was limited, and because they often have comparable operational consequences, these three modes are combined and reported here as “SEFI” in the results section. Because it can be difficult to determine all the effects of such large errors, SBUs and MBUs were determined using only the portion of each run before such a “SEFI” was observed.

The Aerospace Corporation Data Analysis

The Aerospace Heavy ion and proton data were analyzed in a manner similar to GSFC's. Based on the totals for each error type and the fluence accumulated up to the occurrence of the first SEFI or other large error, average cross sections were calculated for all the runs at each effective LET value. Aerospace observed no multi-bit errors and only one run at the highest LET showed a SEFI. Aerospace did additional work to characterize SEFI consequences beyond having bursts of
IV. HEAVY-ION AND PROTON SEE RESULTS

GSFC Results – SEL at NSCL SEETF

SEL was observed only at the highest LET tested (108 MeV\textsuperscript{cm}\textsuperscript{2}/mg) and at elevated temperature (85 °C). Figure 3 shows the measured SEL cross section and the upper limit for the cross section at the next highest LET tested (47 MeV\textsuperscript{cm}\textsuperscript{2}/mg). Although we cannot definitely rule out the possibility of SEL between these two LET values, the low SEL cross section at 108 MeV\textsuperscript{cm}\textsuperscript{2}/mg suggests that the threshold is probably closer to this value rather than the lower limit of the range.

![Fig. 3 SEL cross section and upper limits thereof as a function of effective LET.](image)

Fig. 2. SEL cross section and upper limits thereof as a function of effective LET.

GSFC SEE Results

Figure 4 shows cross sections for SBU, MBU and SEFIs (determined in post processing) as a function of effective LET. It is interesting to note that the MBU cross section (for >1 bit upset) is nearly a constant proportion of the SEU cross section over the high-LET range carried out at the MSU SEETF. Both the SEU and MBU cross section continue to increase up to the highest effective LET tested, while the SEFI cross section appears to saturate over this range. MBUs and “SEFIs” were only observed in the SEETF data (LET> 27 MeV\textsuperscript{cm}\textsuperscript{2}/mg).

Aerospace Results

Figure 5 shows The Aerospace Corporation heavy-ion SEU data from LBNL. The bit-error cross section is approximately 20x higher than the cross section for single-bit errors for the GSFC data on the rev. A die. No MBUs were noted in this data. Seven SEFIs were recorded—but only at the highest LET tested (59.9 MeV\textsuperscript{cm}\textsuperscript{2}/mg) yielding an average cross section of 4.75 \times 10^{-6} \text{ cm}\textsuperscript{2} per device. At least two “SEFI” modes were observed. One mode would be better characterized as a burst error, in which a large number of errors are seen, but recovery can be achieved by simply rewriting the data into the memory. The other mode is properly a SEFI, as power cycling was necessary to recover normal device functionality.

No SEL was seen at room temperature. The upper bound of the 95% confidence level (CL) for SEL cross section is 10^{-6} \text{ cm}\textsuperscript{2}.

![Fig. 4 Cross section vs. LET for heavy ions from data taken by the Aerospace Corporation.](image)

Fig. 4 Cross section vs. LET for heavy ions from data taken by the Aerospace Corporation.

Multiple potential explanations exist on the differences between the GSFC and The Aerospace Corporation’s results. They include:

- Different die revisions (A versus M)
- Different test ion energy/particle ranges (NSCL SEETF and TAMU versus LBNL)
- Thinned die versus unmodified
- Angular effects versus normal incidence

Figure 6 shows The Aerospace Corporation’s proton SEU data for both the 1 Gbit DDR and the preceding generation 512 Mbit DDR from the same vendor. As expected due to geometric cell size issues, the per bit cross sections for the 1 Gbit device are somewhat lower than for the 512 Mbit DDR. All errors observed were isolated single-bit errors—which is not unexpected since all runs were performed with the proton beam incident normal to the device.
protons by Aerospace functioned with no apparent degradation to Fig. 5.

performed once additional test parts are received in August. Proton testing over angles is also anticipated to better characterize susceptibility to multi-bit SEU and other rate sensitivity and pre-irradiation elevated-temperature stress effects in SDRAMs do not show lot-to-lot variation in TID and SEE susceptibility. Additional testing is strongly advised to ensure adequate radiation performance in future applications.

VII. DISCUSSION

Data for the current 1 Gbit 90 nm feature size DDR SDRAMs demonstrate that reduced feature size does not necessarily correlate to worse radiation performance. SEE testing, high-energy ions (e.g. at MSU's SEETF and at TAMU) can be used to obtain a thorough characterization of the device. In carrying out such a strategy, it is helpful to capitalize on the greater LET selectability at TAMU, making use of the SEETF primarily for high-LET ions that cannot be delivered by lower energy facilities. It is also helpful to have a detailed understanding of the overburden the beam must penetrate above the sensitive volume.

VI. FUTURE WORK

While the test results to date are encouraging for use of these memories in space missions, several hurdles remain to be traversed. Full parametric TID testing is scheduled to be performed once additional test parts are received in August. Proton testing over angles is also anticipated to better characterize susceptibility to multi-bit SEU and other proton-induced effects. We also plan to extend our study of volatile memory devices as parts from other vendors and new generations of technology become available.

VIII. CONCLUSION

The radiation performance (SEE and TID) of the Samsung 1-Gbit DDR SDRAMs makes them excellent candidates for space flight applications. SEL susceptibility is low, especially at low temperatures. SEFI susceptibility appears to be comparable to that of previous generations. MBUs were seen at high LET in SEE testing of the rev. A version of the die, but not the rev. M version. The Rev. M version also yielded a higher per bit cross section than the rev. A die. Finally, we note that in the past SDRAMs have shown lot-to-lot variation in TID and SEE susceptibility. Additional testing is strongly advised to ensure adequate radiation performance in future applications.
