temperature as low as about 4 °C at a depth of about 300 m. The cooling would reduce the pressure of the CO₂ remaining in the annular volume to about 44 bars (4.4 MPa) or less. Then a control valve would be opened, allowing CO₂ from the pressurized bladder to expand through a turbine, thus producing electricity for recharging the battery. After flowing through the turbine and the control valve, the CO₂ would enter the annular volume, where it would be condensed at low temperature and pressure, completing the thermodynamic cycle.

Fuel-Cell Power Systems Incorporating Mg-Based H₂G Generators

Hydrogen would be generated from magnesium and steam.

NASA’s Jet Propulsion Laboratory, Pasadena, California

Two hydrogen generators based on reactions involving magnesium and steam have been proposed as means for generating the fuel (hydrogen gas) for such fuel-cell power systems as those to be used in the drive systems of advanced motor vehicles. The hydrogen generators would make it unnecessary to rely on any of the hydrogen-storage systems developed thus far that are, variously, too expensive, too heavy, too bulky, and/or too unsafe to be practical.

The two proposed hydrogen generators are denoted basic and advanced, respectively. In the basic hydrogen generator (see figure), steam at a temperature ≥330 °C would be fed into a reactor charged with magnesium, wherein hydrogen would be released in the exothermic reaction Mg + H₂O → MgO + H₂. The steam would be made in a flash boiler. To initiate the reaction, the boiler could be heated electrically by energy borrowed from a storage battery that would be recharged during normal operation of the associated fuel-cell subsystem. Once the reaction was underway, heat from the reaction would be fed to the boiler. If the boiler were made an integral part of the hydrogen-generator reactor vessel, then the problem of transfer of heat from the reactor to the boiler would be greatly simplified. A pump would be used to feed water from a storage tank to the boiler.

Only a small fraction of the heat generated in the reaction would be needed for boiling: For every kilogram of hydrogen produced, about 44.5 kW h of heat would be generated, while only about 6 kW h would be needed to boil the requisite amount of water. The remaining 38.5 kW h of high-grade heat would have to be dissipated via a radiator. Optionally, the flow of heat from the reactor to the radiator could be intercepted by a thermoelectric converter, thereby increasing the overall electric power generated; the net increase in the overall efficiency of the fuel-cell power system has
been estimated to be equivalent to that afforded by an increase of 19 percent in the amount of hydrogen generated.

The generated hydrogen would be sent through a cooler to reduce its temperature to 80 °C as required for the fuel cells. During operation of a hydrogen-burning fuel cell, water is generated in liquid and vapor forms. The liquid water could easily be recycled to the storage tank. Depending on detailed calculations yet to be performed, it may be advantageous to also recycle the water vapor by condensing it and pumping the resulting liquid water to the storage tank, provided that the weight of the condenser did not exceed the weight of the water saved. At 80 °C, the waste heat from the fuel cell would be of too low a grade to be useful for most purposes; however, if the fuel-cell power system were part of a motor vehicle, the waste heat could be used to heat the passenger compartment in winter.

In the advanced hydrogen generator, the reactor vessel (or one of two or more vessels, depending on the design) would be initially charged with magnesium hydride. The advanced hydrogen generator would exploit two reactions: the aforementioned exothermic reaction at a temperature \( \geq 330 ^\circ C \) plus the endothermic reaction \( \text{MgH}_2 \rightarrow \text{Mg} + \text{H}_2 \), at a temperature \( \geq 300 ^\circ C \). Once the initial heating was complete and both reactions under way, the Mg produced in the endothermic reaction would be consumed in the exothermic reaction, which, in turn, would generate sufficient heat to maintain the endothermic reaction. The main advantages of the advanced hydrogen generator over the basic one would be that (1) it would produce twice the amount of hydrogen for a given amount of magnesium; but (2) the cost of operation is likely to be less than that of the basic hydrogen generator because it is likely that \( \text{MgH}_2 \) could be produced at less than twice the cost of the corresponding amount of Mg.

The main waste product of both the basic and advanced systems would be \( \text{MgO} \), which has extremely low toxicity. \( \text{MgO} \) could be safely and easily recycled in a magnesium-refining plant for less than the cost of Mg because \( \text{MgO} \) is an intermediate product of the refining process.

### Alternative OTEC Scheme for a Submarine Robot

**Expansion/contraction of a wax upon freezing/thawing would be exploited.**

**NASA’s Jet Propulsion Laboratory, Pasadena, California**

A proposed system for exploiting the ocean thermal gradient to generate power would be based on the thawing-expansion/freezeing-contraction behavior of a wax or perhaps another suitable phase-change material. The power generated by this system would be used to recharge the batteries in a battery-powered unmanned underwater vehicle [UUV (essentially, a small exploratory submarine robot)] of a type that has been deployed in large numbers in research pertaining to global warming. A UUV of this type travels between the ocean surface and various depths, measuring temperature and salinity.

This proposed system would be an alternative to another proposed ocean thermal energy conversion (OTEC) system that would serve the same purpose but would utilize a thermodynamic cycle in which \( \text{CO}_2 \) would be the working fluid. That system is described in “Utilizing Ocean Thermal Energy in a Submarine Robot” (NPO-43304), immediately following this brief. The main advantage of this proposed system over the one using \( \text{CO}_2 \) is that it could derive a useful amount of energy from a significantly smaller temperature difference.

At one phase of its operational cycle, the system now proposed would utilize the surface ocean temperature (which

---

**The Wax Would Expand and Contract** upon melting near the ocean surface and freezing at depth, respectively. The expansion and contraction would cause the hydraulic fluid to flow cyclically against the piston to periodically drive the generator to charge the battery.
