manifests itself in the processed image as a bright spot on a dark background (see Figure 2). The moving target is detected computationally as a spot of pixels brighter than a set threshold level. The location of the target is determined, to within a fraction of a pixel, as a brightness-weighted average pixel location. By use of a straightforward transformation that utilizes the image-detector-plane calibration, the target location is converted to azimuth and elevation coordinates, then by use of another calibrated transformation, the azimuth and elevation coordinates are converted to gimbal commands for initial aiming of the narrow-field-of-view camera.

Once the narrow-field-of-view camera has been initially aimed and has acquired an image of the target, the apparatus switches into a tracking mode. In this mode, the gimbal commands are formulated to move the image of the target toward the center of the CCD image plane.

### Visual Data Analysis for Satellites

*Stennis Space Center, Mississippi*

The Visual Data Analysis Package is a collection of programs and scripts that facilitate visual analysis of data available from NASA and NOAA satellites, as well as dropsonde, buoy, and conventional in-situ observations. The package features utilities for data extraction, data quality control, statistical analysis, and data visualization.

The Hierarchical Data Format (HDF) satellite data extraction routines from NASA’s Jet Propulsion Laboratory were customized for specific spatial coverage and file input/output. Statistical analysis includes the calculation of the relative error, the absolute error, and the root mean square error. Other capabilities include curve fitting through the data points to fill in missing data points between satellite passes or where clouds obscure satellite data. For data visualization, the software provides customizable Generic Mapping Tool (GMT) scripts to generate difference maps, scatter plots, line plots, vector plots, histograms, time-series, and color fill images.

*This program was written by Yee Lau, Sachin Bhate, and Patrick Fitzpatrick of the GeoResources Institute at Mississippi State University for Stennis Space Center. ### A Data Type for Efficient Representation of Other Data Types

*NASA’s Jet Propulsion Laboratory, Pasadena, California*

A self-organizing, monomorphic data type denoted a sequence has been conceived to address certain concerns (summarized below) that arise in programming parallel computers. [“Sequence” as used here should not be confused with “sequence” as the word is commonly understood or with “sequence” as used elsewhere to denote another, polymorphic data type that is also relevant to computer programming.] A sequence in the present sense can be regarded abstractly as a vector, set, bag, queue, or other construct. A sequence is defined in terms of the behavior of the operators that can be applied to it without any foreknowledge of the underpinnings of its representation or particular implementation.

Heretofore, in programming a parallel computer, it has been necessary for the programmer to state explicitly, at the
A hand-held instrument that would include an ultrasonic camera has been proposed as an efficient means of reading matrix symbols. The proposed instrument could be operated without mechanical raster scanning. All electronic functions from excitation of ultrasonic pulses through final digital processing for decoding matrix symbols would be performed by dedicated circuitry within the single, compact instrument housing.

The instrument (see figure) would be placed on a selected area on an object of interest believed or suspected to contain a matrix symbol (hereafter denoted, simply, the target). Intimate contact for the purpose of coupling of low-energy ultrasound would be ensured by use of either a flexible membrane camera face or a replaceable gel pad. Ultrasound pulses would be transmitted from a transducer, through the membrane or gel pad, into the target. A portion of each ultrasonic pulse, as modified by any matrix symbol present in the target, would be reflected through the membrane or gel pad to an ultrasound-imaging integrated-circuit chip, which would convert the resulting spatial variation of ultrasound pressure to voltages that could be used to construct a video image of the matrix symbol (if any).

A set of circuit boards above the ultrasound-imaging chip converts the output of the chip into a useful video format and would coordinate timing between the transducer pulses and the acquisition and processing of image data. The system is fully portable and battery powered. The instrument includes the following other boards:

- A pulser board would control the current pulses that drive the acoustic transducer.
- A board comprising a liquid-crystal display unit and its driver circuitry would enable display of the video image in the future. It could include a decoder board that would translate the video image of a matrix symbol into a recog-
