Thermal Expansion of Vacuum Plasma Sprayed Coatings

S.V. Raj and A.R. Palczer
Glenn Research Center, Cleveland, Ohio
Since its founding, NASA has been dedicated to the advancement of aeronautics and space science. The NASA Scientific and Technical Information (STI) program plays a key part in helping NASA maintain this important role.

The NASA STI Program operates under the auspices of the Agency Chief Information Officer. It collects, organizes, provides for archiving, and disseminates NASA's STI. The NASA STI program provides access to the NASA Aeronautics and Space Database and its public interface, the NASA Technical Reports Server, thus providing one of the largest collections of aeronautical and space science STI in the world. Results are published in both non-NASA channels and by NASA in the NASA STI Report Series, which includes the following report types:

- TECHNICAL PUBLICATION. Reports of completed research or a major significant phase of research that present the results of NASA programs and include extensive data or theoretical analysis. Includes compilations of significant scientific and technical data and information deemed to be of continuing reference value. NASA counterpart of peer-reviewed formal professional papers but has less stringent limitations on manuscript length and extent of graphic presentations.

- TECHNICAL MEMORANDUM. Scientific and technical findings that are preliminary or of specialized interest, e.g., quick release reports, working papers, and bibliographies that contain minimal annotation. Does not contain extensive analysis.

- CONTRACTOR REPORT. Scientific and technical findings by NASA-sponsored contractors and grantees.

- CONFERENCE PUBLICATION. Collected papers from scientific and technical conferences, symposia, seminars, or other meetings sponsored or cosponsored by NASA.

- SPECIAL PUBLICATION. Scientific, technical, or historical information from NASA programs, projects, and missions, often concerned with subjects having substantial public interest.

- TECHNICAL TRANSLATION. English-language translations of foreign scientific and technical material pertinent to NASA's mission.

Specialized services also include creating custom thesauri, building customized databases, organizing and publishing research results.

For more information about the NASA STI program, see the following:

- Access the NASA STI program home page at http://www.sti.nasa.gov

- E-mail your question via the Internet to help@sti.nasa.gov

- Fax your question to the NASA STI Help Desk at 443–757–5803

**Thermal Expansion of Vacuum Plasma Sprayed Coatings**

S.V. Raj and A.R. Palczer  
National Aeronautics and Space Administration  
Glenn Research Center  
Cleveland, Ohio 44135

**Abstract**

Metallic Cu-8%Cr, Cu-26%Cr, Cu-8%Cr-1%Al, NiAl and NiCrAlY monolithic coatings were fabricated by vacuum plasma spray deposition processes for thermal expansion property measurements between 293 and 1223 K. The corrected thermal expansion, \((\Delta L/L_0)_{thermal}\), varies with the absolute temperature, \(T\), as

\[(\Delta L/L_0)_{thermal} = A(T - 293)^3 + B(T - 293)^2 + C(T - 293) + D\]

where, \(A\), \(B\), \(C\) and \(D\) are regression constants. Excellent reproducibility was observed for all the coatings except for data obtained on the Cu-8%Cr and Cu-26%Cr coatings in the first heat-up cycle, which deviated from those determined in the subsequent cycles. This deviation is attributed to the presence of residual stresses developed during the spraying of the coatings, which are relieved after the first heat-up cycle. In the cases of Cu-8%Cr and NiAl, the thermal expansion data were observed to be reproducible for three specimens. The linear expansion data for Cu-8%Cr and Cu-26%Cr agree extremely well with rule of mixture (ROM) predictions. Comparison of the data for the Cu-8%Cr coating with literature data for Cr and Cu revealed that the thermal expansion behavior of this alloy is determined by the Cu-rich matrix. The data for NiAl and NiCrAlY are in excellent agreement with published results irrespective of composition and the methods used for processing the materials. The implications of these results on coating GRCop-84 copper alloy combustor liners for reusable launch vehicles are discussed.

**1.0 Introduction**

Many engineering components experience temperature variations during service, which often require the availability of good quality data to ensure that they can be designed reliably and safely to meet the required design objectives. The necessity for generating high quality data is more critical for aerospace components especially those where two or more different materials are bonded to each other to fabricate components with optimized design properties. For example, differences between the thermophysical and mechanical properties of coating materials and the substrate can lead to the development of large residual stresses, which can either distort or debond the coating from the substrate during thermal cycling of a coated component during service.

The National Aeronautics and Space Administration (NASA) has been developing technologies for a new generation of advanced reusable launch vehicles (RLVs) in its efforts to increase its future heavy lift capacity in a more reliable and economical manner compared to the Space Shuttle. Combustion chamber liners in liquid hydrogen (LH₂) fueled-rocket engines experience extreme conditions due to a combination of environmental and thermo-mechanical effects. The combustion flame temperatures in the chamber interior are about 3600 K whereas the backside of the approximately 1 mm thick liner wall experiences cryogenic temperatures of 20 K (Refs. 1 to 6). Uncoated copper and its alloys have been used as combustor liner materials in these regenerative rocket engines because their high thermal conductivities enable efficient heat transfer from the combustion flame to preheat the cryogenic LH₂ flowing in the cooling channels. However, uncoated copper alloy liners undergo environmental degradation due to a combination of the spallation of the locally formed copper oxide scales and “blanching,” which consists of repeated oxidation of the copper matrix and subsequent reduction of the oxide scale (Ref. 6).
The design of the next generation of RLVs calls for using GRCop-84 (Cu-8(at.%)-Cr-4%Nb) copper alloy liners due to its superior properties compared to conventional high conductivity copper alloys, such as NARloy-Z (Refs. 7 to 9). The application of protective coatings on GRCop-84 and other copper alloy substrates can minimize or eliminate many of the problems experienced by uncoated liners and significantly extend their operational lives in RLVs. This factor potentially translates to increased component reliability, shorter depot maintenance time and lower operational cost. In addition, the use of a suitable top coat to act as a thermal barrier can allow the engine to run at higher temperatures thereby resulting in increased thermal efficiency. As a result, several types of ceramic (Refs. 1 and 5) and metallic (Refs. 10 to 15) coatings have been advocated as protective coatings for copper alloy liners. However, the presence of a coating will significantly reduce the thermal conductivity of the liner compared to the uncoated copper alloys, which suggests that metallic coatings are preferred to ceramic coatings.

As mentioned above, the application of coatings on a substrate can result in the development of residual stresses whenever the coated component experiences variations in temperature. These temperature variations can occur during different stages of processing, such as when the sprayed component cools to ambient after vacuum plasma spraying as well as after hot isostatic pressing (HIP) of the component. Differential thermal expansion can also result in thermally induced residual stresses during temperature cycles in service. It is important to note that the surface temperature of the combustion liner is expected to increase from cryogenic temperatures to 800 to 1100 K within 3 sec on starting the engine. As a result, an enormous amount of differential thermal strain can develop in the coated substrate and lead to coating spallation during the transient heat-up portion of the cycle. In order to predict the performance of these coatings in service, as well as to gain insights on the nature and magnitudes of these residual stresses, it is essential to conduct finite element analysis (FEA) to simulate the performance of coated liners in a realistic combustion environment. The reliability of these analyses requires the generation of high quality mechanical and thermophysical property data. Recently, it was demonstrated that CuCrAl and NiCrAlY coatings deposited either by the cold spray or the vacuum plasma spray techniques are potentially viable coatings for GRCop-84 combustion liners (Refs. 14 and 15). However, thermophysical data for these sprayed coatings are either limited or nonexistent in the temperature range of interest for use in RLVs. Although thermal conductivity data of vacuum plasma sprayed NiCrAlY alloys (Refs. 16 and 17) have been previously reported in the literature, it is important to note that these properties are sensitive to compositional and processing variables. Thus, it is essential that thermophysical data be generated on coatings sprayed under processing conditions and for compositions similar to those developed for spraying the GRCop-84 liners in order to ensure reliable design models to be developed.

The objective of this paper is to report the temperature dependence of thermal expansion for vacuum plasma sprayed coatings Cu-Cr, CuCrAl, NiAl and NiCrAlY coating alloys between 293 and 1223 K. The data are analyzed to obtain valuable insights on the behavior of these alloys during heat-up and cool-down thermal cycles.

2.0 Experimental Procedures

2.1 Alloy Composition and Processing

Gas atomized copper alloy powders were procured from Crucible Research, Inc., Pittsburgh, Pennsylvania, whereas the NiAl and NiCrAlY powders were obtained from Homogenous Metals, Inc., New York, and Sulzer Metco, Michigan, respectively. The nominal compositions of the alloy powders were Cu-8(wt.%)-Cr, Cu-26(wt.%)-Cr, Cu-8(wt.%)-Cr-1%Al, Ni-31.5(wt.%)-Al (NiAl), Ni-17(wt.%)-Cr-6%-Al-0.5%Y. Monolithic cylindrical coatings, typically 175 to 250 mm long and 19 to 25 mm thick, were fabricated by spraying the powders on rotating steel mandrels, approximately 25 mm in diameter, by

---

1The term “thermal barrier” is used to signify that the coated copper liners are likely to possess lower thermal conductivity than uncoated copper alloys.
the vacuum plasma spray (VPS) method. The Cu-8%Cr, Cu-8%Cr-1%Al, NiAl and NiCrAlY coatings were deposited by the vacuum plasma spray method at Plasma Processes, Inc., Huntsville, Alabama. The coated mandrels were hot isostatically pressed (HIP) between 1073 and 1273 K under argon gas pressures varying between 100 and 210 MPa for times varying between 1 and 4 hr.

2.2 Thermal Expansion Measurements

Specimens were machined from the HIPed cylinders by electrodischarge machining (EDM). The specimen dimensions for thermal expansion measurements were 25.4 mm long and 6.35 mm in diameter for all coatings except for the Cu-8Cr-1Al alloy specimens, which were 12.7 mm long and 6.35 mm in diameter. The thermal expansion of the specimens was measured between 293 and 1223 K using a NETZSCH Dilatometer Model DIL 402C, which uses a single head design and high purity alumina as a calibration standard. Measurements were made over three heat-cool cycles to minimize the effects of compositional, microstructural and processing inhomogeneities on the data, verify their reproducibility, and statistically average the regression coefficients. The specimen was placed in a sample holder and aligned with a single push-rod with an applied constant load of 0.2 N. The specimens were heated from 293 to 1223 K at 10 K/min. in a He atmosphere flowing at 60 cc/min in the first cycle and furnace cooled to 373 K in the first cool-down cycle. Subsequent cycles consisted of heating and cooling between 373 and 1223 K. The length changes were recorded by a computerized data acquisition system. The experimental strain, $\Delta L/L_0$, where $\Delta L$ is the differential change in length, $L-L_0$, and $L_0$ is the original length of the specimen at room temperature, were measured. Specimen-to-specimen reproducibility measurements were made on three different specimens in the cases of Cu-8%Cr and NiAl.

3.0 Results and Discussion

3.1 Microstructures

The microstructures of the monolithic coatings were nearly fully dense with little visible porosity under an optical microscope. The Cu-26%Cr (Fig. 1(a)) coatings revealed second phase $\alpha$-Cr particles in the matrix at higher magnifications (Fig. 1(b)). The NiCrAlY coating was also nearly fully dense although fine grain boundary porosity was observed at the higher magnifications (> 400 X). The Cu-8%Cr coating was nearly fully dense with very little porosity visible in the microstructures. Similar nearly full dense microstructures were observed in the NiAl and Cu-8%Cr-1%Al coatings.

**Figure 1.**—(a) Low and (b) high magnification views of the optical microstructures of vacuum plasma sprayed Cu-26%Cr monolithic coatings.
3.2 Thermal Expansion

3.2.1 Cu-8%Cr

Figures 2(a) to (c) compare the variation of $\Delta L/L_0$ with $T$, during three heat-up and cool-down cycles for three Cu-8%Cr specimens. For all three specimens, the magnitudes of thermal expansion in the first heat-up cycle were higher than those recorded in subsequent heat-up and cool-down cycles. In contrast, the thermal expansion was nominally identical from the first to the third cool-down cycle although the data for specimen 3 exhibited slightly more scatter (Fig. 2(c)). This observed difference in the magnitudes of $\Delta L/L_0$ between the first and subsequent cycles is most likely due to the presence of multiaxial residual stresses initially developed in the splat-cooled grains of the coating microstructure during processing. The nature and calculation of these residual stresses are fairly involved (Refs. 18 to 20). As a result, the measured values of $(\Delta L/L_0)_{\text{first cycle}}$ for the first heat-up cycle consist of a uniaxial residual strain component and a thermal strain component. Thus,

$$
(\Delta L/L_0)_{\text{first cycle}} = (\Delta L/L_0)_{\text{thermal}} + (\Delta L/L_0)_{\text{residual}}
$$

where $(\Delta L/L_0)_{\text{thermal}}$ and $(\Delta L/L_0)_{\text{residual}}$ are the thermal and residual strains, respectively. Since the temperature dependence of $\Delta L/L_0$ for the first to the third cool-down cycles are nearly identical (Fig. 2(a) to (c)), it is reasonable to assume that the magnitude of $(\Delta L/L_0)_{\text{thermal}}$ can be determined from these data. Subsequently, the temperature dependence of $(\Delta L/L_0)_{\text{residual}}$ can be determined.

The temperature dependence of $(\Delta L/L_0)_{\text{thermal}}$ could be well represented by (Ref. 21)

$$
(\Delta L/L_0)_{\text{thermal}} = A(T - 293)^3 + B(T - 293)^2 + C(T - 293) + D
$$

where A, B, C and D are constants. Table 1 shows the values of these constants determined from a polynomial regression of the experimental data for the three specimens and the corresponding coefficients of determination, $R_d^2$, for each thermal cycle. The magnitudes of the constants determined for the three specimens are similar thereby confirming the reproducibility in the data. The values of $(\Delta L/L_0)_{\text{thermal}}$ were subtracted from the measured values of $(\Delta L/L_0)_{\text{first cycle}}$ to determine the temperature dependence of $(\Delta L/L_0)_{\text{residual}}$ (Fig. 2(a) to (c)).

Figure 2(d) compares the regressed curves$^2$ for the three specimens based on the constants given in Table 1 with literature data for Cr (Ref. 21) and Cu (Ref. 21). The regressed values for the three specimens are in excellent agreement and closely follow the trend exhibited by Cu (Ref. 21) while deviating considerably from the thermal expansion data for Cr (Ref. 21). This is not surprising since Cr has low solubility in Cu (Ref. 22) so that for practical purposes the thermal expansion of Cu-8%Cr should be similar to that of Cu given the relatively low volume fraction, $V_f$, of the $\alpha$-Cr particles ($V_f \sim 9\%$). The excellent agreement between the predicted thermal expansion for the alloy based on a rule of mixtures (ROM) model with the experimental data provides additional confirmation (Fig. 2(d)).

$^2$The regressed curves were corrected for the residual strain offset at room temperature to ensure that $\Delta L/L_0$ values are zero at room temperature. Similar corrections were made for the data for the other coating alloys.
Figure 2.—Temperature variation of $\Delta L/L_0$ and residual strain for three Cu-8%Cr specimens during three heat up-cool down cycles; (a) specimen 1; (b) specimen 2; (c) specimen 3; (d) comparison of the present results with literature data for Cr and Cu [21] as well as with rule of mixture (ROM) predictions.

### 3.2.2 Cu-26%Cr

Figure 3(a) shows the temperature dependence of the thermal expansion for Cu-26%Cr. In contrast to Cu-8%Cr (Fig. 2), the values of $\Delta L/L_0$ for the first heat-up cycle are lower than the measured values for the first cool-down and other subsequent thermal cycles. Figure 3(b) compares the regressed values after correcting for the room temperature residual strain offset with the data for Cr and Cu (Ref. 21), as well as the predicted values from a ROM model ($V_f \approx 30\%$). Equation (2) is an excellent fit to the experimental data, where the regression parameters and values of $R_d^2$, are given in Table 2. Once again, the differences between the first heat-up cycle and the subsequent thermal cycles are attributed to residual stresses developed in the coating during processing. The corresponding temperature dependence of residual strain is also shown in Figure 3(a). The magnitudes of the uniaxial residual strain are compressive in Cu-26%Cr compared to the tensile strains observed in Cu-8%Cr (Figs. 2(a) to (c)), which suggests that there is no simple relationship between the development of residual stresses during processing and the Cr content of the alloys. A comparison of Figures 2(d) and 3(b) reveals that the thermal expansion of Cu-Cr alloy coatings decrease with increasing Cr content consistent with the ROM model.

3.2.3 Cu-8%Cr-1%Al

While Cr solubility in the Cu matrix is negligible in the Cu-Cr alloys (Ref. 22), Al is mainly in solid solution in the Cu matrix in the Cu-Cr-Al system (Refs. 23 and 24). Figure 4(a) shows the temperature dependence of $\Delta L/L_0$ for Cu-8%Cr-1%Al for the first heat-up and subsequent thermal cycles, respectively. Figure 4(b) compares the present results with literature data for Cr and Cu (Ref. 21). The regression parameters using Equation (2) and the corresponding $R^2$ are given in Table 3. The thermal expansion values in the first heat-up cycle are almost identical to those measured in the subsequent thermal cycles indicating that the residual strain is negligible. An examination of Figure 4(b) shows that the thermal expansion of Cu-8%Cr-1%Al is slightly lower than that for Cu and Cu-8%Cr (Fig. 2(d)).

Figure 5.—Temperature variation of $\Delta L/L_0$ and residual strain for three NiAl specimens during three heat up-cool down cycles; (a) Specimen 1; (b) specimen 2; (c) specimen 3; (d) comparison of the present results with literature data for NiAl (Refs. 25 and 26).

### 3.2.4 NiAl

Figures 5(a) to (c) show the temperature dependence of the thermal expansion for three NiAl specimens. The magnitudes of $\Delta L/L_0$ in the first heat-up cycle are nearly identical to those determined in the subsequent thermal cycles similar to the observations on Cu-8%Cr-1%Al (Fig. 4(a)) coatings. Table 4 gives the corresponding regression parameters in Equation (2) and values of $R_d^2$ for the three NiAl specimens. These constants are in excellent agreement thereby suggesting that the specimen-to-specimen variation is negligible (Fig. 5(d)). There are no significant differences between the values of $\Delta L/L_0$ measured during the first heat-up cycle and the other subsequent cool-down and heat-up cycles corresponding to negligible residual strains. Literature data on hot-pressed NiAl (Ref. 25) and hot-extruded NiAl (Ref. 26) are shown for comparison in Figure 5(d). The present data are in excellent agreement with the literature data (Refs. 25 and 26), which suggests that the temperature dependence of thermal expansion of NiAl is not significantly influenced by the processing method.

3.2.5 NiCrAlY

Figure 6 shows the temperature dependence of $\Delta L/L_0$ for the Ni-17%Cr-6%Al-0.5%Y coating and compares it with published data on Ni-20%Cr-11%Al-0.5%Y (Ref. 27). Table 5 gives the regression parameters determined from the first to the third cool-down cycle. Once again, the residual strains are negligible as the values of $\Delta L/L_0$ for all the heat-up and cool-down cycles are similar within the limits of experimental scatter. As shown in Figure 6, the thermal expansion of Ni-17%Cr-6%Al-0.5%Y is slightly larger than Ni-20%Cr-11%Al-0.5%Y (Ref. 27), where the deviation between the two sets of data increases with increasing temperature. Despite the relatively large compositional differences between the two coating alloys, the differences in the values of $\Delta L/L_0$ are sufficiently small to conclude that other NiCrAlY coatings with similar compositions would have comparable $\Delta L/L_0$ values.

3.3 Implications for Coating GRCop-84 Combustion Liners

NiCrAlY and NiAl have been proposed as protective top coats for GRCop-84 rocket engine combustion liners for reusable launch vehicles using Cu-Cr or Cu-Cr-Al bond coats (Ref. 14). Figure 7 compares the thermal expansions for Cu-8%Cr, Cu-26%Cr, Cu-8%Cr-1%Al, NiAl, NiCrAlY and GRCop-84 (Ref. 7). The differences in the magnitudes of thermal expansions between Cu-8%Cr on one hand, and NiAl and NiCrAlY on the other are relatively large, and increase with increasing temperature. These observations suggest that using Cu-8%Cr as a bond coat with either NiAl or NiCrAlY as a top coat on a GRCop-84 substrate is likely to result in the development of large residual thermal stresses when the rocket engine is first fired.
On close examination, it is evident that the thermal expansion characteristics of NiCrAlY and Cu-26%Cr are fairly similar over a wide temperature range, which suggests that the thermal residual stresses would be small when NiCrAlY is used as a top coat with a Cu-26%Cr bond coat. In contrast, the differences in the thermal expansions between a NiAl top coat and a Cu-26%Cr bond coat increase with increasing temperature thereby limiting the use of NiAl as a top coat due to an increased probability of coating spallation at higher temperatures. Despite the similarities in the magnitudes of the thermal expansions of Cu-26%Cr and NiCrAlY, it is important to note that the thermal expansion between the GRCop-84 and Cu-26%Cr increases with increasing temperature. Thus, there is a danger that residual stresses developed at the Cu-26%Cr/GRCop-84 interface could weaken the strength of the bond and lead to coating spallation when NiCrAlY and Cu-26%Cr are used as top and bond coats on a GRCop-84 liner.

Figure 7 shows that the thermal expansion characteristics of the Cu-8%Cr-1%Al coating are almost identical to that for GRCop-84. The addition of 1%Al to Cu-8%Cr results in a very close match in the thermal expansions of Cu-8%Cr-1%Al and GRCop-84. Thus, relatively low residual stresses are likely to develop at the Cu-8%Cr-1%Al/GRCop-84 interface. However, the differences in the thermal expansions between Cu-8%Cr-1%Al and NiAl and NiCrAlY are much larger especially at the higher temperatures, which is likely to lead to the development of significant residual stresses at the bond coat-top coat interfaces.

It is important to note that the magnitude of residual stresses and their effects on coating spallation are determined only partially by differences in thermal expansion between the top coat, bond coat and the GRCop-84 substrate. Other factors, such as elastic modulus, ultimate and yield stress, impurities and microstructures, also influence the magnitudes of the residual stresses and the probability of coating spallation so that precise determination of the local residual stress distribution is often difficult to ascertain. Thermal cycling tests conducted on a NiCrAlY-coated GRCop-84 water-cooled specimen using either a Cu-8%Cr or a Cu-8%Cr-1%Al bond coat under a high heat flux H2/O2 combustion flame did not show any evidence of coating spallation after 40 cycles (Ref. 14). Although the differences in thermal expansions between either the Cu-8%Cr or a Cu-8%Cr-1%Al alloy bond coat and the NiCrAlY alloy top coat increases with increasing temperature, heat transfer analyses of heat fluxes similar to those in a

---

It is important to note that in practice, the Cu-26%Cr coating layer would have residual stresses due to spraying on the substrate prior to the deposition of NiCrAlY top layer, which complicates modeling the residual stresses in a relatively simple manner.
rocket engine reveal that for a top coat thickness of about 0.1 mm, the interface temperatures are likely to be less than 625 K (Ref. 14). Indeed, finite element analyses of the out-of-plane stresses developed during these thermal cycles reveal that their magnitudes are identical under these high heat flux conditions for both Cu-8%Cr and Cu-8%Cr-1%Al bond coats deposited on GRCop-84 substrates using NiCrAlY top coats (Ref. 14). In this case, the out-of-plane stress at the NiCrAlY/bond coat interface increased from –580 to –150 MPa in traversing from the top to the bond coat. The fact that coating spallation did not occur in these high heat flux thermal cycling experiments (Ref. 14) despite the differences in magnitudes of ΔL/L₀ for Cu-8%Cr, Cu-8%Cr-1%Al and NiCrAlY (Fig. 7) suggests that these residual stresses are accommodated by the plasticity of the bond coats.

Although Figure 7 suggests that Cu-26%Cr could be used as suitable bond coat for NiCrAlY top coat, it is important to note that experimental observations revealed that Cu-26%Cr top coats either spalled in cyclic oxidation tests (Ref. 28) or blistered under high heat flux conditions (Ref. 14). Unlike the more ductile NiCrAlY, the brittleness of a NiAl top coat may result in its spallation due to its inability to accommodate any thermal strain mismatch with the Cu-8%Cr-1%Al bond coat. Therefore, it is concluded that Cu-8%Cr-1%Al and NiCrAlY are likely to be the most suitable protective bond and top coat combination for GRCop-84.

Summary and Conclusions

The temperature dependence of the thermal expansion, ΔL/L₀, of vacuum plasma sprayed Cu-8%Cr, Cu-26%Cr, Cu-8%Cr-1%Al, NiAl and Ni-17%Cr-6%Cr-0.5%Al monolithic coatings between 300 and 1223 K are reported. Excellent specimen-to-specimen and cycle-to-cycle reproducibility were observed for all the coatings except during the first heat-up cycle for which the thermal expansion was different than those in the subsequent cycles. The observed behavior could be well represented by the equation:

\[(\Delta L/L_0)_{\text{thermal}} = A(T - 293)^3 + B(T - 293)^2 + C(T - 293) + D.\]

Comparison of the data for Cu-8%Cr and Cu-26%Cr alloy coatings with literature data for Cr and Cu, as well as rule of mixture predictions, revealed that the thermal expansion behaviors of these alloys are determined primarily by the Cu-rich matrix. The data for NiAl are in excellent agreement with published results irrespective of the methods used for processing the materials. It is concluded that the Cu-8%Cr-1%Al coating would be the most suitable bond coat for GRCop-84 with NiCrAlY being the most suitable top coat.

### 14. ABSTRACT

Metallic Cu-8%Cr, Cu-26%Cr, Cu-8%Cr-1%Al, NiAl and NiCrAlY monolithic coatings were fabricated by vacuum plasma spray deposition processes for thermal expansion property measurements between 293 and 1223 K. The corrected thermal expansion, \((DL/L_0)_{\text{thermal}}\) varies with the absolute temperature, \(T\), as \((DL/L_0)_{\text{thermal}} = A(T - 293)^3 + B(T - 293)^2 + C(T - 293) + D\), where, \(A\), \(B\), \(C\) and \(D\) are regression constants. Excellent reproducibility was observed for all of the coatings except for data obtained on the Cu-8%Cr and Cu-26%Cr coatings in the first heat-up cycle, which deviated from those determined in the subsequent cycles. This deviation is attributed to the presence of residual stresses developed during the spraying of the coatings, which are relieved after the first heat-up cycle. In the cases of Cu-8%Cr and NiAl, the thermal expansion data were observed to be reproducible for three specimens. The linear expansion data for Cu-8%Cr and Cu-26%Cr agree extremely well with rule of mixture (ROM) predictions. Comparison of the data for the Cu-8%Cr coating with literature data for Cr and Cu revealed that the thermal expansion behavior of this alloy is determined by the Cu-rich matrix. The data for NiAl and NiCrAlY are in excellent agreement with published results irrespective of composition and the methods used for processing the materials. The implications of these results on coating GRCo-84 copper alloy combustor liners for reusable launch vehicles are discussed.
